Taylor & Francis Group

**The Biomedical Engineering Handbook**  
**Third Edition**

**Medical Devices  
and Systems**

# The Electrical Engineering Handbook Series

*Series Editor*

**Richard C. Dorf**

University of California, Davis

## Titles Included in the Series

*The Handbook of Ad Hoc Wireless Networks*, Mohammad Ilyas

*The Avionics Handbook*, Cary R. Spitzer

*The Biomedical Engineering Handbook, Third Edition*, Joseph D. Bronzino

*The Circuits and Filters Handbook, Second Edition*, Wai-Kai Chen

*The Communications Handbook, Second Edition*, Jerry Gibson

*The Computer Engineering Handbook*, Vojin G. Oklobdzija

*The Control Handbook*, William S. Levine

*The CRC Handbook of Engineering Tables*, Richard C. Dorf

*The Digital Signal Processing Handbook*, Vijay K. Madisetti and Douglas Williams

*The Electrical Engineering Handbook, Third Edition*, Richard C. Dorf

*The Electric Power Engineering Handbook*, Leo L. Grigsby

*The Electronics Handbook, Second Edition*, Jerry C. Whitaker

*The Engineering Handbook, Third Edition*, Richard C. Dorf

*The Handbook of Formulas and Tables for Signal Processing*, Alexander D. Poularikas

*The Handbook of Nanoscience, Engineering, and Technology*, William A. Goddard, III,

Donald W. Brenner, Sergey E. Lyshevski, and Gerald J. Iafrate

*The Handbook of Optical Communication Networks*, Mohammad Ilyas and

Hussein T. Mouftah

*The Industrial Electronics Handbook*, J. David Irwin

*The Measurement, Instrumentation, and Sensors Handbook*, John G. Webster

*The Mechanical Systems Design Handbook*, Osita D.I. Nwokah and Yidirim Hurmuzlu

*The Mechatronics Handbook*, Robert H. Bishop

*The Mobile Communications Handbook, Second Edition*, Jerry D. Gibson

*The Ocean Engineering Handbook*, Ferial El-Hawary

*The RF and Microwave Handbook*, Mike Golio

*The Technology Management Handbook*, Richard C. Dorf

*The Transforms and Applications Handbook, Second Edition*, Alexander D. Poularikas

*The VLSI Handbook*, Wai-Kai Chen

# **The Biomedical Engineering Handbook**

## **Third Edition**

*Edited by*  
**Joseph D. Bronzino**

*Biomedical Engineering Fundamentals*

*Medical Devices and Systems*

*Tissue Engineering and Artificial Organs*

**The Biomedical Engineering Handbook**

# Introduction and Preface

---

During the past five years since the publication of the Second Edition — a two-volume set — of the *Biomedical Engineering Handbook*, the field of biomedical engineering has continued to evolve and expand. As a result, this Third Edition consists of a three volume set, which has been significantly modified to reflect the state-of-the-field knowledge and applications in this important discipline. More specifically, this Third Edition contains a number of completely new sections, including:

- Molecular Biology
- Bionanotechnology
- Bioinformatics
- Neuroengineering
- Infrared Imaging

as well as a new section on ethics.

In addition, all of the sections that have appeared in the first and second editions have been significantly revised. Therefore, this Third Edition presents an excellent summary of the status of knowledge and activities of biomedical engineers in the beginning of the 21st century.

As such, it can serve as an excellent reference for individuals interested not only in a review of fundamental physiology, but also in quickly being brought up to speed in certain areas of biomedical engineering research. It can serve as an excellent textbook for students in areas where traditional textbooks have not yet been developed and as an excellent review of the major areas of activity in each biomedical engineering subdiscipline, such as biomechanics, biomaterials, bioinstrumentation, medical imaging, etc. Finally, it can serve as the “bible” for practicing biomedical engineering professionals by covering such topics as a historical perspective of medical technology, the role of professional societies, the ethical issues associated with medical technology, and the FDA process.

Biomedical engineering is now an important vital interdisciplinary field. Biomedical engineers are involved in virtually all aspects of developing new medical technology. They are involved in the design, development, and utilization of materials, devices (such as pacemakers, lithotripsy, etc.) and techniques (such as signal processing, artificial intelligence, etc.) for clinical research and use; and serve as members of the health care delivery team (clinical engineering, medical informatics, rehabilitation engineering, etc.) seeking new solutions for difficult health care problems confronting our society. To meet the needs of this diverse body of biomedical engineers, this handbook provides a central core of knowledge in those fields encompassed by the discipline. However, before presenting this detailed information, it is important to provide a sense of the evolution of the modern health care system and identify the diverse activities biomedical engineers perform to assist in the diagnosis and treatment of patients.

## Evolution of the Modern Health Care System

Before 1900, medicine had little to offer the average citizen, since its resources consisted mainly of the physician, his education, and his “little black bag.” In general, physicians seemed to be in short

supply, but the shortage had rather different causes than the current crisis in the availability of health care professionals. Although the costs of obtaining medical training were relatively low, the demand for doctors' services also was very small, since many of the services provided by the physician also could be obtained from experienced amateurs in the community. The home was typically the site for treatment and recuperation, and relatives and neighbors constituted an able and willing nursing staff. Babies were delivered by midwives, and those illnesses not cured by home remedies were left to run their natural, albeit frequently fatal, course. The contrast with contemporary health care practices, in which specialized physicians and nurses located within the hospital provide critical diagnostic and treatment services, is dramatic.

The changes that have occurred within medical science originated in the rapid developments that took place in the applied sciences (chemistry, physics, engineering, microbiology, physiology, pharmacology, etc.) at the turn of the century. This process of development was characterized by intense interdisciplinary cross-fertilization, which provided an environment in which medical research was able to take giant strides in developing techniques for the diagnosis and treatment of disease. For example, in 1903, Willem Einthoven, a Dutch physiologist, devised the first electrocardiograph to measure the electrical activity of the heart. In applying discoveries in the physical sciences to the analysis of the biologic process, he initiated a new age in both cardiovascular medicine and electrical measurement techniques.

New discoveries in medical sciences followed one another like intermediates in a chain reaction. However, the most significant innovation for clinical medicine was the development of x-rays. These "new kinds of rays," as their discoverer W.K. Roentgen described them in 1895, opened the "inner man" to medical inspection. Initially, x-rays were used to diagnose bone fractures and dislocations, and in the process, x-ray machines became commonplace in most urban hospitals. Separate departments of radiology were established, and their influence spread to other departments throughout the hospital. By the 1930s, x-ray visualization of practically all organ systems of the body had been made possible through the use of barium salts and a wide variety of radiopaque materials.

X-ray technology gave physicians a powerful tool that, for the first time, permitted accurate diagnosis of a wide variety of diseases and injuries. Moreover, since x-ray machines were too cumbersome and expensive for local doctors and clinics, they had to be placed in health care centers or hospitals. Once there, x-ray technology essentially triggered the transformation of the hospital from a passive receptacle for the sick to an active curative institution for all members of society.

For economic reasons, the centralization of health care services became essential because of many other important technological innovations appearing on the medical scene. However, hospitals remained institutions to dread, and it was not until the introduction of sulfanilamide in the mid-1930s and penicillin in the early 1940s that the main danger of hospitalization, that is, cross-infection among patients, was significantly reduced. With these new drugs in their arsenals, surgeons were able to perform their operations without prohibitive morbidity and mortality due to infection. Furthermore, even though the different blood groups and their incompatibility were discovered in 1900 and sodium citrate was used in 1913 to prevent clotting, full development of blood banks was not practical until the 1930s, when technology provided adequate refrigeration. Until that time, "fresh" donors were bled and the blood transfused while it was still warm.

Once these surgical suites were established, the employment of specifically designed pieces of medical technology assisted in further advancing the development of complex surgical procedures. For example, the Drinker respirator was introduced in 1927 and the first heart-lung bypass in 1939. By the 1940s, medical procedures heavily dependent on medical technology, such as cardiac catheterization and angiography (the use of a cannula threaded through an arm vein and into the heart with the injection of radiopaque dye) for the x-ray visualization of congenital and acquired heart disease (mainly valve disorders due to rheumatic fever) became possible, and a new era of cardiac and vascular surgery was established.

Following World War II, technological advances were spurred on by efforts to develop superior weapon systems and establish habitats in space and on the ocean floor. As a by-product of these efforts, the

development of medical devices accelerated and the medical profession benefited greatly from this rapid surge of technological finds. Consider the following examples:

1. Advances in solid-state electronics made it possible to map the subtle behavior of the fundamental unit of the central nervous system — the neuron — as well as to monitor the various physiological parameters, such as the electrocardiogram, of patients in intensive care units.
2. New prosthetic devices became a goal of engineers involved in providing the disabled with tools to improve their quality of life.
3. Nuclear medicine — an outgrowth of the atomic age — emerged as a powerful and effective approach in detecting and treating specific physiologic abnormalities.
4. Diagnostic ultrasound based on sonar technology became so widely accepted that ultrasonic studies are now part of the routine diagnostic workup in many medical specialties.
5. “Spare parts” surgery also became commonplace. Technologists were encouraged to provide cardiac assist devices, such as artificial heart valves and artificial blood vessels, and the artificial heart program was launched to develop a replacement for a defective or diseased human heart.
6. Advances in materials have made the development of disposable medical devices, such as needles and thermometers, as well as implantable drug delivery systems, a reality.
7. Computers similar to those developed to control the flight plans of the *Apollo* capsule were used to store, process, and cross-check medical records, to monitor patient status in intensive care units, and to provide sophisticated statistical diagnoses of potential diseases correlated with specific sets of patient symptoms.
8. Development of the first computer-based medical instrument, the computerized axial tomography scanner, revolutionized clinical approaches to noninvasive diagnostic imaging procedures, which now include magnetic resonance imaging and positron emission tomography as well.
9. A wide variety of new cardiovascular technologies including implantable defibrillators and chemically treated stents were developed.
10. Neuronal pacing systems were used to detect and prevent epileptic seizures.
11. Artificial organs and tissue have been created.
12. The completion of the genome project has stimulated the search for new biological markers and personalized medicine.

The impact of these discoveries and many others has been profound. The health care system of today consists of technologically sophisticated clinical staff operating primarily in modern hospitals designed to accommodate the new medical technology. This evolutionary process continues, with advances in the physical sciences such as materials and nanotechnology, and in the life sciences such as molecular biology, the genome project and artificial organs. These advances have altered and will continue to alter the very nature of the health care delivery system itself.

## **Biomedical Engineering: A Definition**

*Bioengineering* is usually defined as a basic research-oriented activity closely related to biotechnology and genetic engineering, that is, the modification of animal or plant cells, or parts of cells, to improve plants or animals or to develop new microorganisms for beneficial ends. In the food industry, for example, this has meant the improvement of strains of yeast for fermentation. In agriculture, bioengineers may be concerned with the improvement of crop yields by treatment of plants with organisms to reduce frost damage. It is clear that bioengineers of the future will have a tremendous impact on the qualities of human life. The potential of this specialty is difficult to imagine. Consider the following activities of bioengineers:

- Development of improved species of plants and animals for food production
- Invention of new medical diagnostic tests for diseases

**FIGURE 1** The World of Biomedical Engineering.

- Production of synthetic vaccines from clone cells
- Bioenvironmental engineering to protect human, animal, and plant life from toxicants and pollutants
- Study of protein–surface interactions
- Modeling of the growth kinetics of yeast and hybridoma cells
- Research in immobilized enzyme technology
- Development of therapeutic proteins and monoclonal antibodies

Biomedical engineers, on the other hand, apply electrical, mechanical, chemical, optical, and other engineering principles to understand, modify, or control biologic (i.e., human and animal) systems, as well as design and manufacture products that can monitor physiologic functions and assist in the diagnosis and treatment of patients. When biomedical engineers work within a hospital or clinic, they are more properly called clinical engineers.

## Activities of Biomedical Engineers

The breadth of activity of biomedical engineers is now significant. The field has moved from being concerned primarily with the development of medical instruments in the 1950s and 1960s to include a more wide-ranging set of activities. As illustrated below, the field of biomedical engineering now includes many new career areas (see Figure 1), each of which is presented in this handbook. These areas include:

- Application of engineering system analysis (physiologic modeling, simulation, and control) to biologic problems
- Detection, measurement, and monitoring of physiologic signals (i.e., biosensors and biomedical instrumentation)
- Diagnostic interpretation via signal-processing techniques of bioelectric data
- Therapeutic and rehabilitation procedures and devices (rehabilitation engineering)
- Devices for replacement or augmentation of bodily functions (*artificial organs*)

- Computer analysis of patient-related data and clinical decision making (i.e., medical informatics and artificial intelligence)
- Medical imaging, that is, the graphic display of anatomic detail or physiologic function
- The creation of new biologic products (i.e., *biotechnology* and *tissue engineering*)
- The development of new materials to be used within the body (biomaterials)

Typical pursuits of biomedical engineers, therefore, include:

- Research in new materials for implanted artificial organs
- Development of new diagnostic instruments for blood analysis
- Computer modeling of the function of the human heart
- Writing software for analysis of medical research data
- Analysis of medical device hazards for safety and efficacy
- Development of new diagnostic imaging systems
- Design of telemetry systems for patient monitoring
- Design of biomedical sensors for measurement of human physiologic systems variables
- Development of expert systems for diagnosis of disease
- Design of closed-loop control systems for drug administration
- Modeling of the physiological systems of the human body
- Design of instrumentation for sports medicine
- Development of new dental materials
- Design of communication aids for the handicapped
- Study of pulmonary fluid dynamics
- Study of the biomechanics of the human body
- Development of material to be used as replacement for human skin

Biomedical engineering, then, is an interdisciplinary branch of engineering that ranges from theoretical, nonexperimental undertakings to state-of-the-art applications. It can encompass research, development, implementation, and operation. Accordingly, like medical practice itself, it is unlikely that any single person can acquire expertise that encompasses the entire field. Yet, because of the interdisciplinary nature of this activity, there is considerable interplay and overlapping of interest and effort between them. For example, biomedical engineers engaged in the development of biosensors may interact with those interested in prosthetic devices to develop a means to detect and use the same bioelectric signal to power a prosthetic device. Those engaged in automating the clinical chemistry laboratory may collaborate with those developing expert systems to assist clinicians in making decisions based on specific laboratory data. The possibilities are endless.

Perhaps a greater potential benefit occurring from the use of biomedical engineering is identification of the problems and needs of our present health care system that can be solved using existing engineering technology and systems methodology. Consequently, the field of biomedical engineering offers hope in the continuing battle to provide high-quality care at a reasonable cost. If properly directed toward solving problems related to preventive medical approaches, ambulatory care services, and the like, biomedical engineers can provide the tools and techniques to make our health care system more effective and efficient; and in the process, improve the quality of life for all.

---

**Joseph D. Bronzino** received the B.S.E.E. degree from Worcester Polytechnic Institute, Worcester, MA, in 1959, the M.S.E.E. degree from the Naval Postgraduate School, Monterey, CA, in 1961, and the Ph.D. degree in electrical engineering from Worcester Polytechnic Institute in 1968. He is presently the Vernon Roosa Professor of Applied Science, an endowed chair at Trinity College, Hartford, CT and President of the Biomedical Engineering Alliance and Consortium (BEACON) which is a nonprofit organization consisting of academic and medical institutions as well as corporations dedicated to the development and commercialization of new medical technologies (for details visit [www.beaconalliance.org](http://www.beaconalliance.org)).

He is the author of over 200 articles and 11 books including the following: *Technology for Patient Care* (C.V. Mosby, 1977), *Computer Applications for Patient Care* (Addison-Wesley, 1982), *Biomedical Engineering: Basic Concepts and Instrumentation* (PWS Publishing Co., 1986), *Expert Systems: Basic Concepts* (Research Foundation of State University of New York, 1989), *Medical Technology and Society: An Interdisciplinary Perspective* (MIT Press and McGraw-Hill, 1990), *Management of Medical Technology* (Butterworth/Heinemann, 1992), *The Biomedical Engineering Handbook* (CRC Press, 1st ed., 1995; 2nd ed., 2000; Taylor & Francis, 3rd ed., 2005), *Introduction to Biomedical Engineering* (Academic Press, 1st ed., 1999; 2nd ed., 2005).

Dr. Bronzino is a fellow of IEEE and the American Institute of Medical and Biological Engineering (AIMBE), an honorary member of the Italian Society of Experimental Biology, past chairman of the Biomedical Engineering Division of the American Society for Engineering Education (ASEE), a charter member and presently vice president of the Connecticut Academy of Science and Engineering (CASE), a charter member of the American College of Clinical Engineering (ACCE) and the Association for the Advancement of Medical Instrumentation (AAMI), past president of the IEEE-Engineering in Medicine and Biology Society (EMBS), past chairman of the IEEE Health Care Engineering Policy Committee (HCEPC), past chairman of the IEEE Technical Policy Council in Washington, DC, and presently Editor-in-Chief of Elsevier's BME Book Series and Taylor & Francis' *Biomedical Engineering Handbook*.

Dr. Bronzino is also the recipient of the Millennium Award from IEEE/EMBS in 2000 and the Goddard Award from Worcester Polytechnic Institute for Professional Achievement in June 2004.

Banu Onaral . . . . . 9-1

BIOMEDICAL SIGNAL ANALYSIS CENTERS on the acquisition and processing of information-bearing signals that emanate from living systems. These vital signals permit us to probe the state of the underlying biologic and physiologic structures and dynamics. Therefore, their interpretation has significant diagnostic value for clinicians and researchers.

The detected signals are commonly corrupted with noise. Often, the information cannot be readily extracted from the raw signal, which must be processed in order to yield useful results. Signals and systems engineering knowledge and, in particular, signal-processing expertise are therefore critical in all phases of signal collection and analysis.

Biomedical engineers are called on to conceive and implement processing schemes suitable for biomedical signals. They also play a key role in the design and development of biomedical monitoring devices and systems that match advances in signal processing and instrumentation technologies with biomedical needs and requirements.

This section is organized in two main parts. In the first part, contributing authors review contemporary methods in biomedical signal processing. The second part is devoted to emerging methods that hold the promise for major enhancements in our ability to extract information from vital signals.

The success of signal-processing applications strongly depends on the knowledge about the origin and the nature of the signal. Biomedical signals possess many special properties and hence require special treatment. Also, the need for noninvasive measurements presents unique challenges that demand a clear understanding of biomedical signal characteristics. In the lead chapter, entitled, "Biomedical Signals: Origin and Dynamic Characteristics; Frequency-Domain Analysis," Arnon Cohen provides a general classification of biomedical signals and discusses basics of frequency domain methods.

The advent of digital computing coupled with fast progress in discrete-time signal processing has led to efficient and flexible methods to acquire and treat biomedical data in digital form. The chapter entitled, "Digital Biomedical Signal Acquisition and Processing," by Luca T. Mainardi, Anna M. Bianchi, and Sergio Cerutti, presents basic elements of signal acquisition and processing in the special context of biomedical signals.

Especially in the case of long-term monitoring, digital biomedical signal-processing applications generate vast amounts of data that strain transmission and storage resources. The creation of multipatient reference signal bases also places severe demands on storage. Data compression methods overcome these obstacles by eliminating signal redundancies while retaining clinically significant information. A. Enis Cetin and Hayrettin Köymen provide a comparative overview of a range of approaches from conventional to modern compression techniques suitable for biomedical signals. Futuristic applications involving long-term and ambulatory recording systems, and remote diagnosis opportunities will be made possible by breakthroughs in biomedical data compression. This chapter serves well as a point of departure.

Constraints such as stationarity (and time invariance), gaussianity (and minimum phaseness), and the assumption of a characteristic scale in time and space have constituted the basic, and by now implicit, assumptions upon which the conventional signals and systems theories have been founded. However, investigators engaged in the study of biomedical processes have long known that they did not hold under most realistic situations and hence could not sustain the test of practice.

Rejecting or at least relaxing restrictive assumptions always opens new avenues for research and yields fruitful results. Liberating forces in signals and systems theories have conspired in recent years to create research fronts that target long-standing constraints in the established wisdom (dogma?) of classic signal processing and system analysis. The emergence of new fields in signals and system theories that address these shortcomings and aim to relax these restrictions has been motivated by scientists who, rather

than mold natural behavior into artificial models, seek methods inherently suited to represent reality. Biomedical scientists and engineers are inspired by insights gained from a deeper appreciation for the dynamic richness displayed by biomedical phenomena; hence, more than their counterparts in other disciplines, they more forcefully embrace innovations in signal processing.

One of these novel directions is concerned with time–frequency representations tailored for non-stationary and transient signals. Faye Boudreaux-Bartels and Robin Murray address this issue, provide an introduction to concepts and tools of time–frequency analysis, and point out candidate applications.

Many physiologic structures and dynamics defy the concept of a characteristic spatial and temporal scale and must be dealt with employing methods compatible with their multiscale nature. Judging from the recent success of biomedical signal-processing applications based on time-scale analysis and wavelet transforms, the resolution of many outstanding processing issues may be at hand. The chapter entitled, “Time-Scale Analysis and Wavelets in Biomedical Signals,” by Nitish V. Thakor, familiarizes the reader with fundamental concepts and methods of wavelet analysis and suggests fruitful directions in biomedical signal processing.

The presence of nonlinearities and statistics that do not comply with the gaussianity assumption and the desire for phase reconstruction have been the moving forces behind investigations of higher-order statistics and polyspectra in signal-processing and system-identification fields. An introduction to the topic and potential uses in biomedical signal-processing applications are presented by Athina Petropulu in the chapter entitled, “Higher-Order Spectra in Biomedical Signal Processing.”

Neural networks derive their cue from biologic systems and, in turn, mimic many of the functions of the nervous system. Simple networks can filter, recall, switch, amplify, and recognize patterns and hence serve well many signal-processing purposes. In the chapter entitled, “Neural Networks in Biomedical Signal Processing,” Evangelia Tzanakou helps the reader explore the power of the approach while stressing how biomedical signal-processing applications benefit from incorporating neural-network principles.

The dichotomy between order and disorder is now perceived as a ubiquitous property inherent in the unfolding of many natural complex phenomena. In the last decade, it has become clear that the common threads shared by natural forms and functions are the “physics of disorder” and the “scaling order,” the hallmark of broad classes of fractal entities. Biomedical signals are the global observables of underlying complex physical and physiologic processes. “Complexity” theories therefore hold the potential to provide mathematical tools that describe and possibly shed light on the internal workings of physiologic systems. In the next to last chapter in this section, Banu Onaral and Joseph P. Cammarota introduce the reader to basic tenets of complexity theories and the attendant scaling concepts with hopes to facilitate their integration into the biomedical engineering practice.

The section concludes with a brief chapter on the visions of the future when biomedical signal processing will merge with the rising technologies in telecommunication and multimedia computing, and eventually with virtual reality, to enable remote monitoring, diagnosis, and intervention. The impact of this development on the delivery of health care and the quality of life will no doubt be profound. The promise of biomedical signal analysis will then be fulfilled.

Arnon Cohen  
*Ben-Gurion University*

A signal is a phenomenon that conveys information. Biomedical signals are signals, used in biomedical fields, mainly for extracting information on a biologic system under investigation. The complete process of information extraction may be as simple as a physician estimating the patient’s mean heart rate by feeling, with the fingertips, the blood pressure pulse or as complex as analyzing the structure of internal soft tissues by means of a complex CT machine.

Most often in biomedical applications (as in many other applications), the acquisition of the signal is not sufficient. It is required to process the acquired signal to get the relevant information “buried” in it.

This may be due to the fact that the signal is noisy and thus must be “cleaned” (or in more professional terminology, the signal has to be enhanced) or due to the fact that the relevant information is not “visible” in the signal. In the latter case, we usually apply some transformation to enhance the required information.

The processing of biomedical signals poses some unique problems. The reason for this is mainly the complexity of the underlying system and the need to perform indirect, noninvasive measurements. A large number of processing methods and algorithms is available. In order to apply the best method, the user must know the goal of the processing, the test conditions, and the characteristics of the underlying signal. In this chapter, the characteristics of biomedical signals will be discussed [Cohen, 1986]. Biomedical signals will be divided into characteristic classes, requiring different classes of processing methods. Also in this chapter, the basics of frequency-domain processing methods will be presented.

## 1.1 Origin of Biomedical Signals

---

From the broad definition of the biomedical signal presented in the preceding section, it is clear that biomedical signals differ from other signals only in terms of the application — signals that are used in the biomedical field. As such, biomedical signals originate from a variety of sources. The following is a brief description of these sources:

1. *Bioelectric signals.* The bioelectric signal is unique to biomedical systems. It is generated by nerve cells and muscle cells. Its source is the membrane potential, which under certain conditions may be excited to generate an action potential. In single cell measurements, where specific microelectrodes are used as sensors, the action potential itself is the biomedical signal. In more gross measurements, where, for example, surface electrodes are used as sensors, the electric field generated by the action of many cells, distributed in the electrode’s vicinity, constitutes the bioelectric signal. Bioelectric signals are probably the most important biosignals. The fact that most important biosystems use excitable cells makes it possible to use biosignals to study and monitor the main functions of the systems. The electric field propagates through the biologic medium, and thus the potential may be acquired at relatively convenient locations on the surface, eliminating the need to invade the system. The bioelectric signal requires a relatively simple transducer for its acquisition. A transducer is needed because the electric conduction in the biomedical medium is done by means of ions, while the conduction in the measurement system is by electrons. All these lead to the fact that the bioelectric signal is widely used in most fields of biomedicine.

2. *Bioimpedance signals.* The impedance of the tissue contains important information concerning its composition, blood volume, blood distribution, endocrine activity, automatic nervous system activity, and more. The bioimpedance signal is usually generated by injecting into the tissue under test sinusoidal currents (frequency range of 50 kHz–1 MHz, with low current densities of the order of 20–20 mA). The frequency range is chosen to minimize electrode polarization problems, and the low current densities are chosen to avoid tissue damage mainly due to heating effects. Bioimpedance measurements are usually performed with four electrodes. Two source electrodes are connected to a current source and are used to inject the current into the tissue. The two measurement electrodes are placed on the tissue under investigation and are used to measure the voltage drop generated by the current and the tissue impedance.

3. *Bioacoustic signals.* Many biomedical phenomena create acoustic noise. The measurement of this acoustic noise provides information about the underlying phenomenon. The flow of blood in the heart, through the heart’s valves, or through blood vessels generates typical acoustic noise. The flow of air through the upper and lower airways and in the lungs creates acoustic sounds. These sounds, known as coughs, snores, and chest and lung sounds, are used extensively in medicine. Sounds are also generated in the digestive tract and in the joints. It also has been observed that the contracting muscle produces an acoustic noise (muscle noise). Since the acoustic energy propagates through the biologic medium, the bioacoustic signal may be conveniently acquired on the surface, using acoustic transducers (microphones or accelerometers).

4. *Biomagnetic signals.* Various organs, such as the brain, heart, and lungs, produce extremely weak magnetic fields. The measurements of these fields provides information not included in other biosignals

(such as bioelectric signals). Due to the low level of the magnetic fields to be measured, biomagnetic signals are usually of very low signal-to-noise ratio. Extreme caution must be taken in designing the acquisition system of these signals.

5. *Biomechanical signals.* The term biomechanical signals includes all signals used in the biomedicine fields that originate from some mechanical function of the biologic system. These signals include motion and displacement signals, pressure and tension and flow signals, and others. The measurement of biomechanical signals requires a variety of transducers, not always simple and inexpensive. The mechanical phenomenon does not propagate, as do the electric, magnetic, and acoustic fields. The measurement therefore usually has to be performed at the exact site. This very often complicates the measurement and forces it to be an invasive one.

6. *Biochemical signals.* Biochemical signals are the result of chemical measurements from the living tissue or from samples analyzed in the clinical laboratory. Measuring the concentration of various ions inside and in the vicinity of a cell by means of specific ion electrodes is an example of such a signal. Partial pressures of oxygen ( $pO_2$ ) and carbon dioxide ( $pCO_2$ ) in the blood or respiratory system are other examples. Biochemical signals are most often very low frequency signals. Most biochemical signals are actually dc signals.

7. *Biooptical signals.* Biooptical signals are the result of optical functions of the biologic system, occurring naturally or induced by the measurement. Blood oxygenation may be estimated by measuring the transmitted and backscattered light from a tissue (*in vivo* and *in vitro*) in several wavelengths. Important information about the fetus may be acquired by measuring fluorescence characteristics of the amniotic fluid. Estimation of the heart output may be performed by the dye dilution method, which requires the monitoring of the appearance of recirculated dye in the bloodstream. The development of fiberoptic technology has opened vast applications of biooptical signals.

Table 1.1 lists some of the more common biomedical signals with some of their characteristics.

## 1.2 Classification of Biosignals

---

Biosignals may be classified in many ways. The following is a brief discussion of some of the most important classifications.

1. *Classification according to source.* Biosignals may be classified according to their source or physical nature. This classification was described in the preceding section. This classification may be used when the basic physical characteristics of the underlying process is of interest, for example, when a model for the signal is desired.

2. *Classification according to biomedical application.* The biomedical signal is acquired and processed with some diagnostic, monitoring, or other goal in mind. Classification may be constructed according to the field of application, for example, cardiology or neurology. Such classification may be of interest when the goal is, for example, the study of physiologic systems.

3. *Classification according to signal characteristics.* From point of view of signal analysis, this is the most relevant classification method. When the main goal is processing, it is not relevant what is the source of the signal or to which biomedical system it belongs; what matters are the signal characteristics.

We recognize two broad classes of signals: continuous signals and discrete signals. Continuous signals are described by a continuous function  $s(t)$  which provides information about the signal at any given time. Discrete signals are described by a sequence  $s(m)$  which provides information at a given discrete point on the time axis. Most of the biomedical signals are continuous. Since current technology provides powerful tools for discrete signal processing, we most often transform a continuous signal into a discrete one by a process known as sampling. A given signal  $s(t)$  is sampled into the sequence  $s(m)$  by

$$s(m) = s(t)|_{t=mT_s} \quad m = \dots, -1, 0, 1, \dots \quad (1.1)$$

TABLE 1.1 Biomedical Signals

Classification	Acquisition	Frequency range	Dynamic range	Comments
<i>Bioelectric</i>				
Action potential	Microelectrodes	100 Hz–2 kHz	10 $\mu$ V–100 mV	Invasive measurement of cell membrane potential
Electroneurogram (ENG)	Needle electrode	100 Hz–1 kHz	5 $\mu$ V–10 mV	Potential of a nerve bundle
Electroretinogram (ERG)	Microelectrode	0.2–200 Hz	0.5 $\mu$ V–1 mV	Evoked flash potential
Electro-oculogram (EOG)	Surface electrodes	dc–100 Hz	10 $\mu$ V–5 mV	Steady-corneal-retinal potential
Electroencephalogram (EEG)	Surface electrodes	0.5–100 Hz	2–100 $\mu$ V	Multichannel (6–32) scalp potential
Delta range		0.5–4 Hz		Young children, deep sleep and pathologies
Theta range		4–8 Hz		Temporal and central areas during alert states
Alpha range		8–13 Hz		Awake, relaxed, closed eyes
Beta range		13–22 Hz		
Sleep spindles		6–15 Hz	50–100 $\mu$ V	Bursts of about 0.2–0.6 sec
K-complexes		12–14 Hz	100–200 $\mu$ V	Bursts during moderate and deep sleep
Evoked potentials (EP)	Surface electrodes		0.1–20 $\mu$ V	Response of brain potential to stimulus
Visual (VEP)		1–300 Hz	1–20 $\mu$ V	Occipital lobe recordings, 200-msec duration
Somatosensory (SEP)		2 Hz–3 kHz		Sensory cortex
Auditory (AEP)		100 Hz–3 kHz	0.5–10 $\mu$ V	Vertex recordings
Electrocorticogram	Needle electrodes	100 Hz–5 kHz		Recordings from exposed surface of brain
Electromyography (EMG)				
Single-fiber (SFEMG)	Needle electrode	500 Hz–10 kHz	1–10 $\mu$ V	Action potentials from single muscle fiber
Motor unit action potential (MUAP)	Needle electrode	5 Hz–10 kHz	100 $\mu$ V–2 mV	
Surface EMG (SEMG)	Surface electrodes			
Skeletal muscle		2–500 Hz	50 $\mu$ V–5 mV	
Smooth muscle		0.01–1 Hz		
Electrocardiogram (ECG)	Surface electrodes	0.05–100 Hz	1–10 mV	
High-frequency ECG	Surface electrodes	100 Hz–1 kHz	100 $\mu$ V–2 mV	Notches and slus waveforms superimposed on the ECG

where  $T_s$  is the sampling interval and  $f_s = 2\pi/T_s$  is the sampling frequency. Further characteristic classification, which applies to continuous as well as discrete signals, is described in Figure 1.1.

We divide signals into two main groups: deterministic and stochastic signals. Deterministic signals are signals that can be exactly described mathematically or graphically. If a signal is deterministic and its mathematical description is given, it conveys no information. Real-world signals are never deterministic. There is always some unknown and unpredictable noise added, some unpredictable change in the parameters, and the underlying characteristics of the signal that render it nondeterministic. It is, however, very often convenient to approximate or model the signal by means of a deterministic function.

An important family of deterministic signals is the periodic family. A periodic signal is a deterministic signal that may be expressed by

$$s(t) = s(t + nT) \quad (1.2)$$

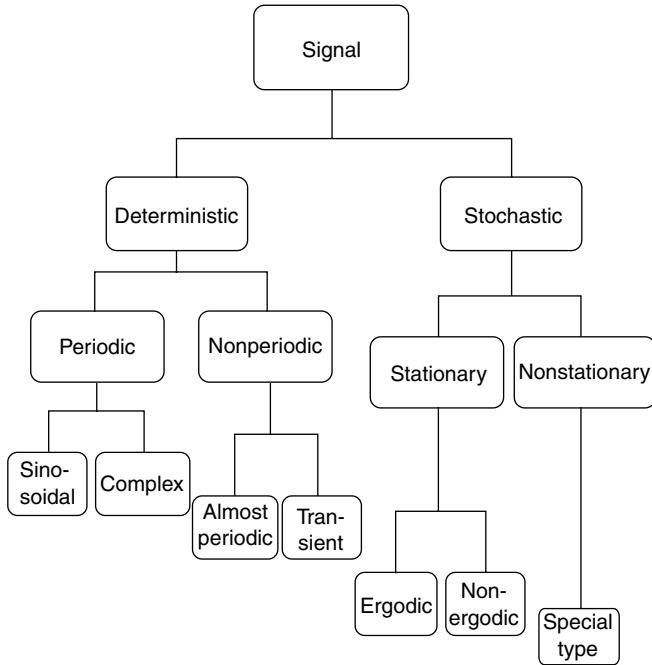

FIGURE 1.1 Classification of signals according to characteristics.

where  $n$  is an integer and  $T$  is the period. The periodic signal consists of a basic wave shape with a duration of  $T$  seconds. The basic wave shape repeats itself an infinite number of times on the time axis. The simplest periodic signal is the sinusoidal signal. Complex periodic signals have more elaborate wave shapes. Under some conditions, the blood pressure signal may be modeled by a complex periodic signal, with the heart rate as its period and the blood pressure wave shape as its basic wave shape. This is, of course, a very rough and inaccurate model.

Most deterministic functions are nonperiodic. It is sometimes worthwhile to consider an “almost periodic” type of signal. The ECG signal can sometimes be considered “almost periodic.” The ECG’s RR interval is never constant; in addition, the PQRST complex of one heartbeat is never exactly the same as that of another beat. The signal is definitely nonperiodic. Under certain conditions, however, the RR interval is almost constant, and one PQRST is almost the same as the other. The ECG may thus sometimes be modeled as “almost periodic.”

### 1.3 Stochastic Signals

The most important class of signals is the stochastic class. A stochastic signal is a sample function of a stochastic process. The process produces sample functions, the infinite collection of which is called the ensemble. Each sample function differs from the other in its fine details; however, they all share the same distribution probabilities. Figure 1.2 depicts three sample functions of an ensemble. Note that at any given time, the values of the sample functions are different.

Stochastic signals cannot be expressed exactly; they can be described only in terms of probabilities which may be calculated over the ensemble. Assuming a signal  $s(t)$ , the  $N$ th-order joint probability function

$$P[s(t_1) \leq s_1, s(t_2) \leq s_2, \dots, s(t_N) \leq s_N] = P(s_1, s_2, \dots, s_N) \quad (1.3)$$

FIGURE 1.2 The ensemble of the stochastic process  $s(t)$ .

is the joint probability that the signal at time  $t_i$  will be less than or equal to  $S_i$  and at time  $t_j$  will be less than or equal to  $S_j$ , etc. This joint probability describes the statistical behavior and intradependence of the process. It is very often useful to work with the derivative of the joint probability function; this derivative is known as the joint probability density function (PDF):

$$p(s_1, s_2, \dots, s_N) = \frac{\partial^N}{\partial s_1 \partial s_2 \dots \partial s_N} [P(s_1, s_2, \dots, s_N)] \tag{1.4}$$

Of particular interest are the first- and second-order PDFs.

The expectation of the process  $s(t)$ , denoted by  $E\{s(t)\}$  or by  $m_s$ , is a statistical operator defined as

$$E\{s(t)\} = \int_{-\infty}^{\infty} sp(s) ds = m \tag{1.5}$$

The expectation of the function  $s^n(t)$  is known as the *n*th-order moment. The first-order moment is thus the expectation of the process. The *n*th-order moment is given by

$$E\{s^n(t)\} = \int_{-\infty}^{\infty} s^n p(s) ds \tag{1.6}$$

Another important statistical operator is the *n*th central moment:

$$\mu_n = E\{(s - m_s)^n\} = \int_{-\infty}^{\infty} (s - m_s)^n p(s) ds \quad (1.7)$$

The second central moment is known as the *variance* (the square root of which is the standard deviation). The variance is denoted by  $\sigma^2$ :

$$\sigma^2 = \mu_2 = E\{(s - m_s)^2\} = \int_{-\infty}^{\infty} (s - m_s)^2 p(s) ds \quad (1.8)$$

The second-order joint moment is defined by the joint PDF. Of particular interest is the autocorrelation function  $r_{ss}$ :

$$r_{ss}(t_1, t_2) = E\{s(t_1)s(t_2)\} = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} s(t_1)s(t_2)p(s_1, s_2) ds_1 ds_2 \quad (1.9)$$

The cross-correlation function is defined as the second joint moment of the signal  $s$  at time  $t_1$ ,  $s(t_1)$ , and the signal  $y$  at time  $t_2$ ,  $y(t_2)$ :

$$r_{sy}(t_1, t_2) = E\{s(t_1)y(t_2)\} = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} s(t_1)y(t_2)p(s_1, y_2) ds_1 dy_2 \quad (1.10)$$

Stationary stochastic processes are processes whose statistics do not change in time. The expectation and the variance (as with any other statistical mean) of a stationary process will be time-independent. The autocorrelation function, for example, of a stationary process will thus be a function of the time difference  $t = t_2 - t_1$  (one-dimensional function) rather than a function of  $t_2$  and  $t_1$  (two-dimensional function).

Ergodic stationary processes possess an important characteristic: Their statistical probability distributions (along the ensemble) equal those of their time distributions (along the time axis of any one of its sample functions). For example, the correlation function of an ergodic process may be calculated by its definition (along the ensemble) or along the time axis of any one of its sample functions:

$$r_{ss}(\tau) = E\{s(t)s(t - \tau)\} = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T s(t)s(t - \tau) dt \quad (1.11)$$

The right side of Equation 1.11 is the time autocorrelation function.

Ergodic processes are nice because one does not need the ensemble for calculating the distributions; a single sample function is sufficient. From the point of view of processing, it is desirable to model the signal as an ergodic one. Unfortunately, almost all signals are nonstationary (and hence nonergodic). One must therefore use nonstationary processing methods (such as, for e.g., wavelet transformation) which are relatively complex or cut the signals into short-duration segments in such a way that each may be considered stationary.

The sleep EEG signal, for example, is a nonstationary signal. We may consider segments of the signal, in which the subject was at a given sleep state, as stationary. In order to describe the signal, we need to estimate its probability distributions. However, the ensemble is unavailable. If we further assume that the process is ergodic, the distributions may be estimated along the time axis of the given sample function. Most of the standard processing techniques assume the signal to be stationary and ergodic.

## 1.4 Frequency-Domain Analysis

Until now we have dealt with signals represented in the time domain, that is to say, we have described the signal by means of its value on the time axis. It is possible to use another representation for the

same signal: that of the frequency domain. Any signal may be described as a continuum of sine waves having different amplitudes and phases. The frequency representation describes the signals by means of the amplitudes and phases of the sine waves. The transformation between the two representations is given by the *Fourier transform* (FT):

$$S(\omega) = \int_{-\infty}^{\infty} s(t)e^{-j\omega t} dt = F\{s(t)\} \tag{1.12}$$

where  $\omega = 2\pi f$  is the angular frequency, and  $F\{*\}$  is the Fourier operator.

The *inverse Fourier transform* (IFT) is the operator that transforms a signal from the frequency domain into the time domain:

$$s(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} S(\omega)e^{j\omega t} d\omega = F^{-1}\{S(\omega)\} \tag{1.13}$$

The frequency domain representation  $S(\omega)$  is complex; hence

$$S(\omega) = |S(\omega)|e^{j\theta(\omega)} \tag{1.14}$$

where  $|S(\omega)|$ , the absolute value of the complex function, is the amplitude spectrum, and  $\theta(\omega)$ , the phase of the complex function, is the phase spectrum. The square of the absolute value,  $|S(\omega)|^2$ , is termed the power spectrum. The power spectrum of a signal describes the distribution of the signal's power on the frequency axis. A signal in which the power is limited to a finite range of the frequency axis is called a band-limited signal. Figure 1.3 depicts an example of such a signal.

The signal in Figure 1.3 is a band-limited signal; its power spectrum is limited to the frequency range  $-\omega_{\max} \leq \omega \leq \omega_{\max}$ . It is easy to show that if  $s(t)$  is real (which is the case in almost all applications), the amplitude spectrum is an even function and the phase spectrum is an odd function.

Special attention must be given to stochastic signals. Applying the FT to a sample function would provide a sample function on the frequency axis. The process may be described by the ensemble of spectra. Another alternative to the frequency representation is to consider the correlation function of the process. This function is deterministic. The FT may be applied to it, yielding a deterministic frequency function. The FT of the correlation function is defined as the power spectral density function (PSD):

$$\text{PSD}[s(t)] = S_{ss}(\omega) = F\{r_{ss}(\tau)\} = \int_{-\infty}^{\infty} r_{ss}(\tau)e^{-j\omega\tau} d\tau \tag{1.15}$$

FIGURE 1.3 Example of a signal described in the time and frequency domains.

The PSD is used to describe stochastic signals; it describes the density of power on the frequency axis. Note that since the autocorrelation function is an even function, the PSD is real; hence no phase spectrum is required.

The EEG signal may serve as an example of the importance of the PSD in signal processing. When processing the EEG, it is very helpful to use the PSD. It turns out that the power distribution of the EEG changes according to the physiologic and psychological states of the subject. The PSD may thus serve as a tool for the analysis and recognition of such states.

Very often we are interested in the relationship between two processes. This may be the case, for example, when two sides of the brain are investigated by means of EEG signals. The time-domain expression of such relationships is given by the cross-correlation function (Equation 1.10). The frequency-domain representation of this is given by the FT of the cross-correlation function, which is called the cross-power spectral density function (C-PSD) or the cross-spectrum:

$$S_{sy}(\omega) = F\{r_{sy}(\tau)\} = |S_{sy}(\omega)|e^{j\theta_{sy}(\omega)} \quad (1.16)$$

Note that we have assumed the signals  $s(t)$  and  $y(t)$  are stationary; hence the cross-correlation function is not a function of time but of the time difference  $t$ . Note also that unlike the autocorrelation function,  $r_{sy}(\tau)$  is not even; hence its FT is not real. Both absolute value and phase are required.

It can be shown that the absolute value of the C-PSD is bounded:

$$|S_{sy}(\omega)|^2 \leq S_{ss}(\omega)S_{yy}(\omega) \quad (1.17)$$

The absolute value information of the C-PSD may thus be normalized to provide the coherence function:

$$\gamma_{sy}^2 = \frac{|S_{sy}(\omega)|^2}{S_{ss}(\omega)S_{yy}(\omega)} \leq 1 \quad (1.18)$$

The coherence function is used in a variety of biomedical applications. It has been used, for example, in EEG analysis to investigate brain asymmetry.

## 1.5 Discrete Signals

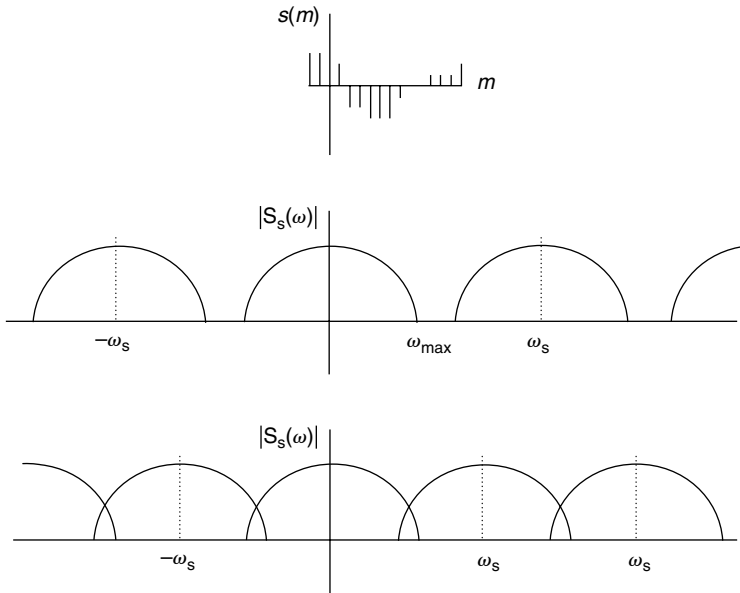

Assume now that the signal  $s(t)$  of Figure 1.3 was sampled using a sampling frequency of  $f_s = \omega_s/2\pi = 2\pi/T_s$ . The sampled signal is the sequence  $s(m)$ . The representation of the sampled signal in the frequency domain is given by applying the Fourier operator:

$$S_s(\omega) = F\{s(m)\} = |S_s(\omega)|e^{j\theta_s(\omega)} \quad (1.19)$$

The amplitude spectrum of the sampled signal is depicted in Figure 1.4. It can easily be proven that the spectrum of the sampled signal is the spectrum of the original signal repeated infinite times at frequencies of  $n\omega_s$ . The spectrum of a sampled signal is thus a periodic signal in the frequency domain. It can be observed, in Figure 1.4, that provided the sampling frequency is large enough, the wave shapes of the spectrum do not overlap. In such a case, the original (continuous) signal may be extracted from the sampled signal by low-pass filtering. A low-pass filter with a cutoff frequency of  $\omega_{\max}$  will yield at its output only the first period of the spectrum, which is exactly the continuous signal. If, however, the sampling frequency is low, the wave shapes overlap, and it will be impossible to regain the continuous signal.

The sampling frequency must obey the inequality

$$\omega_s \geq 2\omega_{\max} \quad (1.20)$$

**FIGURE 1.4** Amplitude spectrum of a sampled signal with sampling frequency above the Nyquist frequency (upper trace) and below the Nyquist frequency (lower trace).

Equation 1.20 is known as the sampling theorem, and the lowest allowable sampling frequency is called the Nyquist frequency. When overlapping does occur, there are errors between the sampled and original signals. These errors are known as aliasing errors. In practical applications, the signal does not possess a finite bandwidth; we therefore limit its bandwidth by an antialiasing filter prior to sampling.

The discrete Fourier transform (DFT) [Proakis and Manolakis, 1988] is an important operator that maps a finite sequence  $s(m), m = 0, 1, \dots, N - 1$ , into another finite sequence  $S(k), k = 0, 1, \dots, N - 1$ . The DFT is defined as

$$S(k) = \text{DFT}\{s(m)\} = \sum_{m=0}^{N-1} s(m)e^{-jkm} \tag{1.21}$$

An inverse operator, the inverse discrete Fourier transform (IDFT), is an operator that transforms the sequence  $S(k)$  back into the sequence  $s(m)$ . It is given by

$$s(m) = \text{IDFT}\{S(k)\} = \frac{1}{N} \sum_{k=0}^{N-1} S(k)e^{jkm} \tag{1.22}$$

It can be shown that if the sequence  $s(m)$  represents the samples of the band-limited signal  $s(t)$ , sampled under Nyquist conditions with sampling interval of  $T_s$ , the DFT sequence  $S(k)$  (neglecting windowing effects) represents the samples of the FT of the original signal:

$$S(k) = S_s(\omega)|_{\omega=k(\omega_s/N)} \quad k = 0, 1, \dots, N - 1 \tag{1.23}$$

Figure 1.5 depicts the DFT and its relations to the FT. Note that the  $N$  samples of the DFT span the frequency range one period. Since the amplitude spectrum is even, only half the DFT samples carry the information; the other half is composed of the complex conjugates of the first half.

FIGURE 1.5 The sampled signal  $s(m)$  and its DFT.

The DFT may be calculated very efficiently by means of the fast (discrete) Fourier transform (FFT) algorithm. It is this fact that makes the DFT an attractive means for FT estimation. The DFT provides an estimate for the FT with frequency resolution of

$$\Delta f = \frac{2\pi f_s}{N} = \frac{2\pi}{T} \tag{1.24}$$

where  $T$  is the duration of the data window. The resolution may be improved by using a longer window. In cases where it is not possible to have a longer data window, for example, because the signal is not stationary, zero padding may be used. The sequence may be augmented with zeroes:

$$s_A(m) = \{s(0), s(1), \dots, s(N - 1), 0, \dots, 0\} \tag{1.25}$$

$$w(t) = 0 \quad \forall |t| > T/2 \tag{1.25a}$$

The zero padded sequence  $s_A(m)$ ,  $m = 0, 1, \dots, L - 1$ , contains  $N$  elements of the original sequence and  $L - N$  zeroes. It can be shown that its DFT represents the samples of the FT with an increased resolution of  $\Delta f = 2\pi f_s L - 1$ .

## 1.6 Data Windows

Calculation of the various functions previously defined, such as the correlation function, requires knowledge of the signal from minus infinity to infinity. This is, of course, impractical because the signal is not available for long durations and the results of the calculations are expected at a reasonable time. We therefore do not use the signal itself but the windowed signal.

A window  $w(t)$  is defined as a real and even function that is also time-limited:

The FT of a window  $W(\omega)$  is thus real and even and is not band-limited.

Multiplying a signal by a window will zero the signal outside the window duration (the observation period) and will create a windowed, time-limited signal  $s_w(t)$ :

$$s_w(t) = s(t)w(t) \quad (1.26)$$

In the frequency domain, the windowed signal will be

$$S_w(\omega) = S(\omega) * W(\omega) \quad (1.27)$$

where  $(*)$  is the convolution operator. The effect of windowing on the spectrum of the signal is thus the convolution with the FT of the window. A window with very narrow spectrum will cause low distortions. A practical window has an FT with a main lobe, where most of its energy is located, and sidelobes, which cover the frequency axis. The convolution of the sidelobes with the FT of the signal causes distortions known as spectral leakage. Many windows have been suggested for a variety of applications.

The simplest window is the rectangular (Dirichlet) window; in its discrete form it is given by  $w(m) = 1$ ,  $m = 0, 1, \dots, N - 1$ . A more useful window is the Hamming window, given by

$$w(m) = 0.54 - 0.46 \cos\left(\frac{2\pi}{N} m\right) \quad m = 0, 1, \dots, N - 1 \quad (1.28)$$

The Hamming window was designed to minimize the effects of the first sidelobe.

## 1.7 Short-Time Fourier Transform

The Fourier analysis discussed in preceding sections assumed that the signal is stationary. Unfortunately, most signals are nonstationary. A relatively simple way to deal with the problem is to divide the signal into short segments. The segments are chosen such that each one by itself can be considered a windowed sample of a stationary process. The duration of the segments has to be determined either by having some a priori information about the signal or by examining its local characteristics. Depending on the signal and the application, the segments may be of equal or different duration.

We want to represent such a segmented signal in the frequency domain. We define the short-time Fourier transform (STFT):

$$\text{STFT}_s(\omega, \tau) = F\{s(t)w(t - \tau)\} = \int_{-\infty}^{\infty} s(t)w(t - \tau)e^{-j\omega t} dt \quad (1.29)$$

The window is shifted on the time axis to  $t = \tau$  so that the FT is performed on a windowed segment in the range  $t - (T/2) \leq t \leq t + (T/2)$ . The STFT describes the amplitude and phase-frequency distributions of the signal in the vicinity of  $t = \tau$ .

In general, the STFT is a two-dimensional, time-frequency function. The resolution of the STFT on the time axis depends on the duration  $T$  of the window. The narrower the window, the better the time resolution. Unfortunately, choosing a short-duration window means a wider-band window. The wider the window in the frequency domain, the larger the spectral leakage and hence the deterioration of the frequency resolution. One of the main drawbacks of the STFT method is the fact that the time and frequency resolutions are linked together. Other methods, such as the wavelet transform, are able to better deal with the problem.

In highly nonstationary signals, such as speech signals, equal-duration windows are used. Window duration is on the order of 10–20 msec. In other signals, such as the EEG, variable-duration windows are used. In the EEG, windows on the order of 5–30 sec are often used.

FIGURE 1.6 A spectrogram.

A common way for representing the two-dimensional STFT function is by means of the spectrogram. In the spectrogram, the time and frequency axes are plotted, and the STFT PSD value is given by the gray-scale code or by a color code. Figure 1.6 depicts a simple spectrogram. The time axis is quantized to the window duration  $T$ . The gray scale codes the PSD such that black denotes maximum power and white denotes zero power. In Figure 1.6, the PSD is quantized into only four levels of gray. The spectrogram shows a signal that is nonstationary in the time range  $0$  to  $8T$ . In this time range, the PSD possesses a peak that is shifted from about  $0.6f_s$  to about  $0.1f_s$  at time  $0.7T$ . From time  $0.8T$ , the signal becomes stationary with a PSD peak power in the low-frequency range and the high-frequency range.

## 1.8 Spectral Estimation

The PSD is a very useful tool in biomedical signal processing. It is, however, impossible to calculate, since it requires infinite integration time. Estimation methods must be used to acquire an estimate of the PSD from a given finite sample of the process under investigation. Many algorithms for spectral estimation are available in the literature [Kay, 1988], each with its advantages and drawbacks. One method may be suitable for processes with sharp spectral peaks, while another will perform best for broad, smoothed spectra. An a priori knowledge on the type of PSD one is investigating helps in choosing the proper spectral estimation method. Some of the PSD estimation methods will be discussed here.

### 1.8.1 The Blackman–Tukey Method

This method estimates the PSD directly from its definition (Equation 1.15) but uses finite integration time and an estimate rather than the true correlation function. In its discrete form, the PSD estimation is

$$\hat{S}_{xx}(\omega) = T_s \sum_{m=-M}^M \hat{r}_{xx}(m) e^{-j\omega m T_s} \quad (1.30)$$

$$\hat{r}_{xx}(m) = \frac{1}{N} \sum_{i=0}^{N-i-1} x(m+i)x(i)$$

where  $N$  is the number of samples used for the estimation of the correlation coefficients, and  $M$  is the number of correlation coefficients used for estimation of the PSD. Note that a biased estimation of the correlation is employed. Note also that once the correlations have been estimated, the PSD may be calculated by applying the FFT to the correlation sequence.

### 1.8.2 The Periodogram

The periodogram estimates the PSD directly from the signal without the need to first estimate the correlation. It can be shown that

$$S_{xx}(\omega) = \lim_{T \rightarrow \infty} E \left\{ \frac{1}{2T} \left| \int_{-T}^T x(t) e^{-j\omega t} dt \right|^2 \right\} \tag{1.31}$$

The PSD presented in Equation 1.31 requires infinite integration time. The periodogram estimates the PSD from a finite observation time by dropping the lim operator. It can be shown that in its discrete form, the periodogram estimator is given by

$$\hat{S}_{xx}(\omega) = \frac{T_s}{N} |\text{DFT}\{x(m)\}|^2 \tag{1.32}$$

The great advantage of the periodogram is that the DFT operator can very efficiently be calculated by the FFT algorithm.

A modification to the periodogram is weighted overlapped segment averaging (WOSA). Rather than using one segment of  $N$  samples, we divide the observation segment into shorter subsegments, perform a periodogram for each one, and then average all periodograms. The WOSA method provides a smoother estimate of the PSD.

### 1.8.3 Time-Series Analysis Methods

Time-series analysis methods model the signal as an output of a linear system driven by a white source. Figure 1.7 depicts this model in its discrete form. Since the input is a white noise process (with zero mean and unity variance), the PSD of the signal is given by

$$S_{ss}(\omega) = |H(\omega)|^2 \tag{1.33}$$

The PSD of the signal may thus be represented by the system’s transfer function. Consider a general pole-zero system with  $p$  poles and  $q$  zeros [ARMA( $p, q$ )]:

$$H(z) = \frac{\sum_{i=0}^q b_i z^{-i}}{1 + \sum_{i=1}^p a_i z^{-i}} \tag{1.34}$$

Its absolute value evaluated on the frequency axis is

$$|H(\omega)|^2 = \left. \frac{|\sum_{i=0}^q b_i z^{-i}|^2}{|\sum_{i=1}^p a_i z^{-i}|^2} \right|_{z=e^{-j\omega T_s}} \tag{1.35}$$

Several algorithms are available for the estimation of the model’s coefficients. The estimation of the ARMA model parameters requires the solution of a nonlinear set of equations. The special case of  $q = 0$ , namely, an all-pole model [AR( $p$ )], may be estimated by means of linear equations. Efficient AR estimation

FIGURE 1.7 Time-series model for the signal  $s(m)$ .

**FIGURE 1.8** PSD of surface EMG. (Upper trace) Blackman–Tukey (256 correlation coefficients and 256 padding zeroes). (Middle trace) Periodogram (512 samples and 512 padding zeroes). (Lower trace) AR model ( $p = 40$ ).

algorithms are available, making it a popular means for PSD estimation. Figure 1.8 shows the estimation of EMG PSD using several estimation methods.

## 1.9 Signal Enhancement

The biomedical signal is very often a weak signal contaminated by noise. Consider, for example, the problem of monitoring the ECG signal. The signal is acquired by surface electrodes that pick up the electric potential generated by the heart muscle. In addition, the electrodes pick up potentials from other active muscles. When the subject is at rest, this type of noise may be very small, but when the subject is an athlete performing some exercise, the muscle noise may become dominant. Additional noise may enter the system from electrodes motion, from the power lines, and from other sources. The first task of processing is usually to enhance the signal by “cleaning” the noise without (if possible) distorting the signal.

Assume a simple case where the measured signal  $x(t)$  is given by

$$x(t) = s(t) + n(t) \quad X(\omega) = S(\omega) + N(\omega) \quad (1.36)$$

where  $s(t)$  is the desired signal and  $n(t)$  is the additive noise. For simplicity, we assume that both the signal and noise are band-limited, namely, for the signal,  $S(\omega) = 0$ , for  $\omega_{\max} \leq \omega, \omega_{\min} \geq \omega$ . Figure 1.9 depicts the PSD of the signal in two cases, the first where the PSD of the signal and noise do not overlap and the second where they do overlap (for the sake of simplicity, only the positive frequency axis was plotted). We want to enhance the signal by means of linear filtering. The problem is to design the linear filter that will

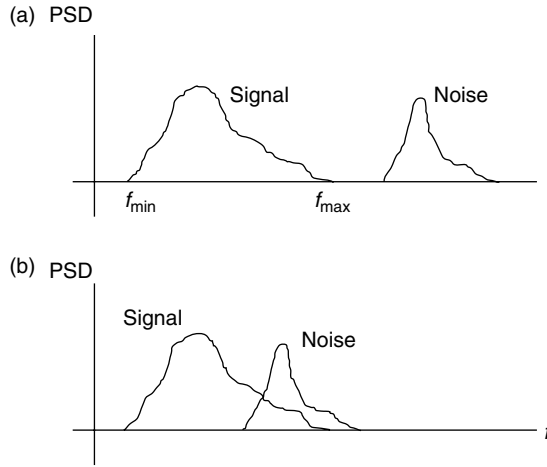

FIGURE 1.9 Noisy signal in the frequency domain (a) nonoverlapping case and (b) overlapping case.

provide best enhancement. Assuming we have the filter, its output, the enhanced signal, is given by

$$y(t) = x(t) * h(t) \quad Y(\omega) = X(\omega)H(\omega) \tag{1.37}$$

where  $y(t) = \hat{s}(t) + n_o(t)$  is the enhanced output, and  $h(t)$  is the impulse response of the filter. The solution for the first case is trivial; we need an ideal bandpass filter whose transfer function  $H(\omega)$  is

$$H(\omega) = \begin{cases} 1, & \omega_{\min} < \omega < \omega_{\max} \\ 0, & \text{otherwise} \end{cases} \tag{1.38}$$

Such a filter and its output are depicted in Figure 1.10.

As is clearly seen in Figure 1.10, the desired signal  $s(t)$  was completely recovered from the given noisy signal  $x(t)$ . Practically, we do not have ideal filters, so some distortions and some noise contamination will always appear at the output. With the correct design, we can approximate the ideal filter so that the distortions and noise may be as small as we desire. The enhancement of overlapping noisy signals is far from being trivial.

## 1.10 Optimal Filtering

When the PSD of signal and noise overlap, complete, undistorted recovery of the signal is impossible. Optimal processing is required, with the first task being definition of the optimality criterion. Different criteria will result in different solutions to the problem. Two approaches will be presented here: the Wiener filter and the matched filter.

### 1.10.1 Minimization of Mean Squared Error: The Wiener Filter

Assume that our goal is to estimate, at time  $t + \xi$ , the value of the signal  $s(t + \xi)$ , based on the observations  $x(t)$ . The case  $\xi = 0$  is known as smoothing, while the case  $\xi > 0$  is called prediction.

**FIGURE 1.10** (a) An ideal bandpass filter. (b) Enhancement of a nonoverlapping noisy signal by an ideal bandpass filter.

We define an output error  $\varepsilon(t)$  as the error between the filter’s output and the desired output. The expectation of the square of the error is given by

$$\begin{aligned}
 E\{e^2(t)\} &= E\{[s(t + \xi) - y(t + \xi)]^2\} \\
 &= E\left\{\left[s(t + \xi) - \int_{-\infty}^{\infty} h(\tau)x(t - \tau) d\tau\right]^2\right\}
 \end{aligned}
 \tag{1.39}$$

The integral term on the right side of Equation 1.39 is the convolution integral expressing the output of the filter.

The minimization of Equation 1.39 with respect of  $h(t)$  yields the optimal filter (in the sense of minimum squared error). The minimization yields the Wiener–Hopf equation:

$$r_{sx}(\tau + \xi) = \int_{-\infty}^{\infty} h(\eta)r_{xx}(\tau - \eta) d\eta
 \tag{1.40}$$

In the frequency domain, this equation becomes

$$S_{sx}(\omega)e^{j\omega\xi} = H_{\text{opt}}(\omega)S_{xx}(\omega)
 \tag{1.41}$$

from which the optimal filter  $H_{\text{opt}}(\omega)$  can be calculated:

$$H_{\text{opt}}(\omega) = \frac{S_{sx}(\omega)}{S_{xx}(\omega)}e^{j\omega\xi} = \frac{S_{sx}(\omega)}{S_{ss}(\omega) + S_{nn}(\omega)}e^{j\omega\xi}
 \tag{1.42}$$

If the signal and noise are uncorrelated and either the signal or the noise has zero mean, the last equation becomes

$$H_{\text{opt}}(\omega) = \frac{S_{ss}(\omega)}{S_{ss}(\omega) + S_{nn}(\omega)} e^{j\omega\xi} \quad (1.43)$$

The optimal filter requires a priori knowledge of the PSD of noise and signal. These are very often not available and must be estimated from the available signal. The optimal filter given in Equation 1.42 and Equation 1.43 is not necessarily realizable. In performing the minimization, we have not introduced a constraint that will ensure that the filter is causal. This can be done, yielding the realizable optimal filter.

### 1.10.2 Maximization of the Signal-to-Noise Ratio: The Matched Filter

The Wiener filter was optimally designed to yield an output as close as possible to the signal. In many cases we are not interested in the fine details of the signal but only in the question whether the signal exists at a particular observation or not. Consider, for example, the case of determining the heart rate of a subject under noisy conditions. We need to detect the presence of the R wave in the ECG. The exact shape of the wave is not important. For this case, the optimality criterion used in the last section is not suitable. To find a more suitable criterion, we define the output signal-to-noise ratio: Let us assume that the signal  $s(t)$  is a deterministic function. The response of the filter,  $\hat{s}(t) = s(t) * h(t)$ , to the signal is also deterministic. We shall define the output signal-to-noise ratio

$$\text{SNR}_o(t) = \frac{\hat{s}(t)}{E\{n_o^2(t)\}} \quad (1.44)$$

as the optimality criterion. The optimal filter will be the filter that maximizes the output SNR at a certain given time  $t = t_0$ . The maximization yields the following integral equation:

$$\int_0^T h(\xi) r_{nn}(\tau - \xi) d\xi = as(t_0 - \tau) \quad 0 \leq \tau < T \quad (1.45)$$

where  $T$  is the observation time and  $a$  is any constant. This equation has to be solved for any given noise and signal.

A special important case is the case where the noise is a white noise so that its autocorrelation function is a delta function. In this case, the solution of Equation 1.45 is

$$h(\tau) = \frac{1}{N} s(t_0 - \tau) \quad (1.46)$$

where  $N$  is the noise power. For this special case, the impulse response of the optimal filter has the form of the signal run backward, shifted to the time to . This type of filter is called a matched filter.

## 1.11 Adaptive Filtering

The optimal filters discussed in the preceding section assumed the signals to be stationary with known PSD. Both assumptions rarely occur in reality. In most biomedical applications, the signals are nonstationary with unknown PSD. To enhance such signals, we require a filter that will continuously adjust itself to perform optimally under the changing circumstances. Such a filter is called an adaptive filter [Widrow and Stearns, 1985].

The general description of an adaptive filter is depicted in Figure 1.11. The signal  $s(t)$  is to be corrected according to the specific application. The correction may be enhancement or some reshaping. The signal is given in terms of the noisy observation signal  $x(t)$ . The main part of the system is a filter, and the

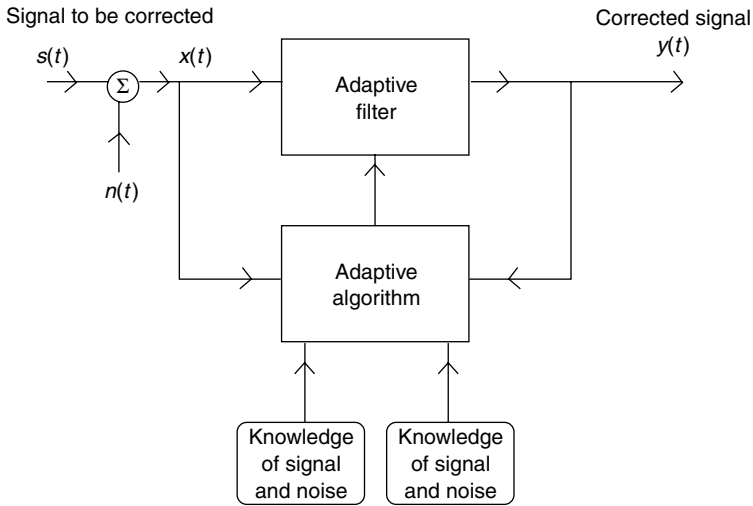

FIGURE 1.11 Adaptive filter, general scheme.

parameters (gain, poles, and zeroes) are controllable by the adaptive algorithm. The adaptive algorithm has some a priori information on the signal and the noise (the amount and type of information depend on the application). It also has a correction criterion, according to which the signal is operating. The adaptive algorithm also gets the input and output signals of the filter so that its performance can be analyzed continuously.

The adaptive filter requires a correction algorithm. This can best be implemented digitally. Most adaptive filters therefore are implemented by means of computers or special digital processing chips.

An important class of adaptive filters requires a reference signal. The knowledge of the noise required by this type of adaptive filter is a reference signal that is correlated with the noise. The filter thus has two inputs: the noisy signal  $x(t) = s(t) + n(t)$  and the reference signal  $nR(t)$ . The adaptive filter, functioning as a noise canceler, estimates the noise  $n(t)$  and, by subtracting it from the given noisy input, gets an estimate for the signal. Hence

$$y(t) = x(t) - \hat{n}(t) = s(t) + [n(t) - \hat{n}(t)] = \hat{s}(t) \tag{1.47}$$

The output of the filter is the enhanced signal. Since the reference signal is correlated with the noise, the following relationship exists:

$$N_R(\omega) = G(\omega)N(\omega) \tag{1.48}$$

which means that the reference noise may be represented as the output of an unknown filter  $G(\omega)$ . The adaptive filter estimates the inverse of this unknown noise filter and from its estimates the noise:

$$\hat{n}(t) = F^{-1}\{\hat{G}^{-1}(\omega)N_R(\omega)\} \tag{1.49}$$

The estimation of the inverse filter is done by the minimization of some performance criterion. There are two dominant algorithms for the optimization: the recursive least squares (RLS) and the least mean squares (LMS). The LMS algorithm will be discussed here.

FIGURE 1.12 Block diagram of LMS adaptive noise canceler.

Consider the mean square error

$$\begin{aligned}
 E\{\varepsilon^2(t)\} &= E\{y^2(t)\} = E\{(s(t) + [n(t) - \hat{n}(t)])^2\} \\
 &= E\{s^2(t)\} + E\{[n(t) - \hat{n}(t)]^2\}
 \end{aligned}
 \tag{1.50}$$

The right side of Equation 1.50 is correct, assuming that the signal and noise are uncorrelated. We are searching for the estimate  $\hat{G}^{-1}(\omega)$  that will minimize the mean square error:  $E\{[n(t) - \hat{n}(t)]^2\}$ . Since the estimated filter affects only the estimated noise, the minimization of the noise error is equivalent to the minimization of Equation 1.50. The implementation of the LMS filter will be presented in its discrete form (see Figure 1.12).

The estimated noise is

$$\hat{n}_R(m) = \sum_{i=0}^p v_i w_i = \mathbf{v}_m^T \mathbf{w}
 \tag{1.51}$$

where

$$\begin{aligned}
 \mathbf{v}_m^T &= [v_0, v_1, \dots, v_p] = [1, n_R(m-1), \dots, n_R(m-p)] \\
 \mathbf{w}^T &= [w_0, w_1, \dots, w_p]
 \end{aligned}
 \tag{1.52}$$

The vector  $\mathbf{w}$  represents the filter. The steepest descent minimization of Equation 1.50 with respect to the filter's coefficients  $\mathbf{w}$  yields the iterative algorithm

$$\mathbf{w}_{j+1} = \mathbf{w}_j + 2\mu e_j \mathbf{v}_j \quad (1.53)$$

where  $m$  is a scalar that controls the stability and convergence of the algorithm. In the evaluation of Equation 1.53, the assumption

$$\frac{\partial E\{e_j^2\}}{\partial w_k} \cong \frac{\partial e_j^2}{\partial w_k} \quad (1.54)$$

was made. This is indeed a drastic approximation; the results, however, are very satisfactory. Figure 1.12 depicts the block diagram of the LMS adaptive noise canceler.

The LMS adaptive noise canceler has been applied to many biomedical problems, among them cancellation of power-line interferences, elimination of electrosurgical interferences, enhancement of fetal ECG, noise reduction for the hearing impaired, and enhancement of evoked potentials.

## 1.12 Segmentation of Nonstationary Signals

Most biomedical signals are nonstationary, yet the common processing techniques (such as the FT) deal with stationary signals. The STFT is one method of processing nonstationary signals, but it does require, however, the segmentation of the signal into "almost" stationary segments. The signal is thus represented as a piecewise-stationary signal.

An important problem in biomedical signal processing is efficient segmentation. In very highly nonstationary signals, such as the speech signal, short, constant-duration (of the order of 15 msec) segments are used. The segmentation processing in such a case is simple and inexpensive. In other cases such as the monitoring of nocturnal EEG, a more elaborate segmentation procedure is called for because the signal may consist of "stationary" segments with very wide duration range. Segmentation into a priori fixed-duration segments will be very inefficient in such cases.

Several adaptive segmentation algorithms have been suggested. Figure 1.13 demonstrates the basic idea of these algorithms. A fixed reference window is used to define an initial segment of the signal. The duration of the reference window is determined such that it is long enough to allow a reliable PSD estimate yet short enough so that the segment may still be considered stationary. Some a priori information about the signal will help in determining the reference window duration. A second, sliding window is shifted along the signal. The PSD of the segment defined by the sliding window is estimated at each window position. The two spectra are compared using some spectral distance measure. As long as this distance measure remains below a certain decision threshold, the reference segment and the sliding segment are considered close enough and are related to the same stationary segment. Once the distance measure exceeds the decision threshold, a new segment is defined. The process continues by defining the last sliding window as the reference window of the new segment.

Let us define a relative spectral distance measure

$$D_t(\omega) = \int_{\omega_M}^{\omega_M} \left( \frac{S_R(\omega) - S_t(\omega)}{S_R(\omega)} \right)^2 \quad (1.55)$$

where  $S_R(\omega)$  and  $S_t(\omega)$  are the PSD estimates of the reference and sliding segments, respectively, and  $\omega_M$  is the bandwidth of the signal. A normalized spectral measure was chosen, since we are interested in differences in the shape of the PSD and not in the gain.

Some of the segmentation algorithms use growing reference windows rather than fixed ones. This is depicted in the upper part of Figure 1.13. The various segmentation methods differ in the way the PSDs are

**FIGURE 1.13** Adaptive segmentation of simulated EEG. First 2.5 sec and last 2.5 sec were simulated by means of different AR models. (Lower trace) SEM calculated with fixed reference window. A new segment has been detected at  $t = 2.5$ . (From Cohen, 1986, with permission.)

estimated. Two of the more well-known segmentation methods are the auto-correlation measure method (ACM) and the spectral error measure (SEM).

Biologic signals carry information that is useful for comprehension of the complex pathophysiologic mechanisms underlying the behavior of living systems. Nevertheless, such information cannot be available directly from the raw recorded signals; it can be masked by other biologic signals contemporaneously detected (endogenous effects) or buried in some additive noise (exogenous effects). For such reasons, some additional processing is usually required to enhance the relevant information and to extract from it parameters that quantify the behavior of the system under study, mainly for physiologic studies, or that define the degree of pathology for routine clinical procedures (diagnosis, therapy, or rehabilitation).

Several processing techniques can be used for such purposes (they are also called preprocessing techniques); time- or frequency-domain methods including filtering, **averaging**, spectral estimation, and others. Even if it is possible to deal with continuous time waveforms, it is usually convenient to convert them into a numerical form before processing. The recent progress of digital technology, in terms of both hardware and software, makes digital rather than analog processing more efficient and flexible. Digital techniques have several advantages: their performance is generally powerful, being able to easily implement even complex algorithms, and accuracy depends only on the truncation and round-off errors, whose effects can be predicted and controlled by the designer and are largely unaffected by other unpredictable variables such as component aging and temperature, which can degrade the performances of analog devices. Moreover, design parameters can be more easily changed because they involve software rather than hardware modifications.

A few basic elements of signal acquisition and processing will be presented in the following; our aim is to stress mainly the aspects connected with acquisition and analysis of biologic signals, leaving to the cited

FIGURE 2.1 General block diagram of the acquisition procedure of a digital signal.

literature a deeper insight into the various subjects for both the fundamentals of digital signal processing and the applications.

## 2.1 Acquisition

A schematic representation of a general acquisition system is shown in Figure 2.1. Several physical magnitudes are usually measured from biologic systems. They include electromagnetic quantities (currents, potential differences, field strengths, etc.), as well as mechanical, chemical, or generally nonelectrical variables (pressure, temperature, movements, etc.). Electric signals are detected by sensors (mainly electrodes), while nonelectric magnitudes are first converted by transducers into electric signals that can be easily treated, transmitted, and stored. Several books of biomedical instrumentation give detailed descriptions of the various transducers and the hardware requirements associated with the acquisition of the different biologic signals [Tompkins and Webster, 1981; Cobbold, 1988; Webster, 1992].

An analog preprocessing block is usually required to amplify and filter the signal (in order to make it satisfy the requirements of the hardware such as the dynamic of the analog-to-digital converter), to compensate for some unwanted sensor characteristics, or to reduce the portion of undesired noise. Moreover, the continuous-time signal should be bandlimited before analog-to-digital (A/D) conversion. Such an operation is needed to reduce the effect of **aliasing** induced by sampling, as will be described in the next section. Here it is important to remember that the acquisition procedure should preserve the information contained in the original signal waveform. This is a crucial point when recording biologic signals, whose characteristics often may be considered by physicians as indices of some underlying pathologies (i.e., the ST-segment displacement on an ECG signal can be considered a marker of ischemia, the peak-and-wave pattern on an EEG tracing can be a sign of epilepsy, and so on). Thus the acquisition system should not introduce any form of distortion that can be misleading or can destroy real pathologic alterations. For this reason, the analog prefiltering block should be designed with constant modulus and linear phase (or zero-phase) **frequency response**, at least in the passband, over the frequencies of interest. Such requirements make the signal arrive undistorted up to the A/D converter.

The analog waveform is then A/D converted into a digital signal; that is, it is transformed into a series of numbers, discretized both in time and amplitude, that can be easily managed by digital processors. The A/D conversion ideally can be divided in two steps, as shown in Figure 2.1: the sampling process, which converts the continuous signal in a discrete-time series and whose elements are named samples, and a quantization procedure, which assigns the amplitude value of each sample within a set of determined discrete values. Both processes modify the characteristics of the signal, and their effects will be discussed in the following sections.

### 2.1.1 The Sampling Theorem

The advantages of processing a digital series instead of an analog signal have been reported previously. Furthermore, the basic property when using a sampled series instead of its continuous waveform lies in the fact that the former, under certain hypotheses, is completely representative of the latter. When this happens, the continuous waveform can be perfectly reconstructed just from the series of sampled

**FIGURE 2.2** Effect of sampling frequency ( $f_s$ ) on a band-limited signal (up to frequency  $f_b$ ). Fourier transform of the original time signal (a), of the sampled signal when  $f_s < 2f_b$  (b), and when  $f_s > 2f_b$  (c). The dark areas in part (b) indicate the aliased frequencies.

values. This is known as the sampling theorem (or Shannon theorem) [Shannon, 1949]. It states that a continuous-time signal can be completely recovered from its samples if, and only if, the sampling rate is greater than twice the signal bandwidth.

In order to understand the assumptions of the theorem, let us consider a continuous band-limited signal  $x(t)$  (up to  $f_b$ ) whose Fourier transform  $X(f)$  is shown in Figure 2.2a and suppose to uniformly sample it. The sampling procedure can be modeled by the multiplication of  $x(t)$  with an impulse train

$$i(t) = \sum_{k=-\infty, \infty} \delta(t - kT_s) \tag{2.1}$$

where  $\delta(t)$  is the delta (Dirac) function,  $k$  is an integer, and  $T_s$  is the sampling interval. The sampled signal becomes

$$x_s(t) = x(t) \cdot i(t) = \sum_{k=-\infty, \infty} x(t) \cdot \delta(t - kT_s) \tag{2.2}$$

Taking into account that multiplication in time domain implies convolution in frequency domain, we obtain

$$X_s(f) = X(f) \cdot I(f) = X(f) \cdot \frac{1}{T_s} \sum_{k=-\infty, \infty} \delta(f - kf_s) = \frac{1}{T_s} \sum_{k=-\infty, \infty} X(f - kf_s) \tag{2.3}$$

where  $f_s = 1/T_s$  is the sampling frequency.

Thus  $X_s(f)$ , that is, the Fourier transform of the sampled signal, is periodic and consists of a series of identical repeats of  $X(f)$  centered around multiples of the sampling frequency, as depicted in Figure 2.2b,c.

**FIGURE 2.3** Power spectrum of an EEG signal (originally bandlimited up to 40 Hz). The presence of 50-Hz mains noise (a) causes aliasing error in the 30-Hz component (i.e., in the  $\beta$  diagnostic band) in the sampled signal (b) if  $f_s = 80$  Hz.

It is worth noting in Figure 2.2b that the frequency components of  $X(f)$  placed above  $f_s/2$  appears, when  $f_s < 2f_b$ , as folded back, summing up to the lower-frequency components. This phenomenon is known as aliasing (higher component look “alias” lower components). When aliasing occurs, the original information (Figure 2.2a) cannot be recovered because the frequency components of the original signal are irreversibly corrupted by the overlaps of the shifted versions of  $X(f)$ .

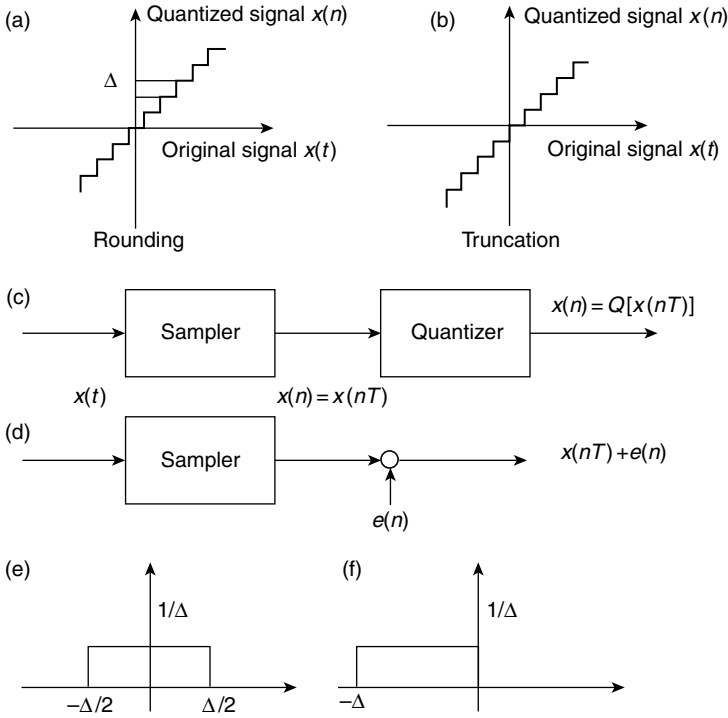

A visual inspection of Figure 2.2 allows one to observe that such frequency contamination can be avoided when the original signal is bandlimited ( $X(f) = 0$ , for  $f > f_b$ ) and sampled at a frequency  $f_s \geq 2f_b$ . In this case, shown in Figure 2.2c, no overlaps exist between adjacent reply of  $X(f)$ , and the original waveform can be retrieved by low-pass filtering the sampled signal [Oppenheim and Schaffer, 1975]. Such observations are the basis of the sampling theorem previously reported.

The hypothesis of a bandlimited signal is hardly verified in practice, due to the signal characteristics or to the effect of superimposed wideband noise. It is worth noting that filtering before sampling is always needed even if we assume the incoming signal to be bandlimited. Let us consider the following example of an EEG signal whose frequency content of interest ranges between 0 and 40 Hz (the usual diagnostic bands are  $\delta$ , 0 to 3.5 Hz;  $\nu$ , 4 to 7 Hz,  $\alpha$ , 8 to 13 Hz;  $\beta$ , 14 to 40 Hz). We may decide to sample it at 80 Hz, thus literally respecting the Shannon theorem. If we do it without prefiltering, we could find some unpleasant results. Typically, the 50-Hz mains noise will replicate itself in the signal band (30 Hz, i.e., the  $\beta$  band), thus corrupting irreversibly the information, which is of great interest from a physiologic and clinical point of view. The effect is shown in Figure 2.3a (before sampling) and Figure 2.3b (after sampling). Generally, it is advisable to sample at a frequency greater than  $2f_b$  [Gardenhire, 1964] in order to take into account the nonideal behavior of the filter or the other preprocessing devices. Therefore, the prefiltering block of Figure 2.1 is always required to bandlimit the signal before sampling and to avoid aliasing errors.

### 2.1.2 The Quantization Effects

The quantization produces a discrete signal, whose samples can assume only certain values according to the way they are coded. Typical step functions for a uniform quantizer are reported in Figure 2.4a,b, where the quantization interval  $\Delta$  between two quantization levels is evidenced in two cases: rounding and truncation, respectively.

Quantization is a heavily nonlinear procedure, but fortunately, its effects can be statistically modeled. Figure 2.4c,d shows it; the nonlinear quantization block is substituted by a statistical model in which the error induced by quantization is treated as an additive noise  $e(n)$  (**quantization error**) to the signal  $x(n)$ .

**FIGURE 2.4** Nonlinear relationships for rounding (a) and truncation (b) quantization procedures. Description of quantization block (c) by a statistical model (d) and probability densities for the quantization noise  $e(n)$  for rounding (e) and truncation (f).  $\Delta$  is the quantization interval.

The following hypotheses are considered in order to deal with a simple mathematical problem:

1.  $e(n)$  is supposed to be a white noise with uniform distribution
2.  $e(n)$  and  $x(n)$  are uncorrelated

First of all, it should be noted that the probability density of  $e(n)$  changes according to the adopted coding procedure. If we decide to round the real sample to the nearest quantization level, we have  $-\Delta/2 \leq e(n) < \Delta/2$ , while if we decide to truncate the sample amplitude, we have  $-\Delta \leq e(n) < 0$ . The two probability densities are plotted in Figure 2.4e,f.

The two ways of coding yield processes with different statistical properties. In the first case the mean and variance value of  $e(n)$  are

$$m_e = 0 \quad \sigma_e^2 = \Delta^2/12$$

while in the second case  $m_e = -\Delta/2$ , and the variance is still the same. Variance reduces in the presence of a reduced quantization interval as expected.

Finally, it is possible to evaluate the signal-to-noise ratio (SNR) for the quantization process:

$$\text{SNR} = 10 \log_{10} \left( \frac{\sigma_x^2}{\sigma_e^2} \right) = 10 \log_{10} \left( \frac{\sigma_x^2}{2^{-2b}/12} \right) = 6.02b + 10.79 + 10 \log_{10}(\sigma_x^2) \quad (2.4)$$

having set  $\Delta = 2^{-2b}$  and where  $\sigma_x^2$  is the variance of the signal and  $b$  is the number of bits used for coding. It should be noted that the SNR increases by almost 6 dB for each added bit of coding. Several forms of quantization are usually employed: uniform, nonuniform (preceding the uniform sampler with

a nonlinear block), or roughly (small number of quantization levels and high quantization step). Details can be found in Carassa [1983], Jaeger [1982], and Widrow [1956].

## 2.2 Signal Processing

A brief review of different signal-processing techniques will be given in this section. They include traditional filtering, averaging techniques, and spectral estimators.

Only the main concepts of analysis and design of digital filters are presented, and a few examples are illustrated in the processing of the ECG signal. Averaging techniques will then be described briefly and their usefulness evidenced when noise and signal have similar frequency contents but different statistical properties; an example for evoked potentials enhancement from EEG background noise is illustrated. Finally, different spectral estimators will be considered and some applications shown in the analysis of RR fluctuations (i.e., the heart rate variability (HRV) signal).

### 2.2.1 Digital Filters

A digital filter is a discrete-time system that operates some transformation on a digital input signal  $x(n)$  generating an output sequence  $y(n)$ , as schematically shown by the block diagram in Figure 2.5. The characteristics of transformation  $T[\cdot]$  identify the filter. The filter will be time-variant if  $T[\cdot]$  is a function of time or time-invariant otherwise, while is said to be *linear* if, and only if, having  $x_1(n)$  and  $x_2(n)$  as inputs producing  $y_1(n)$  and  $y_2(n)$ , respectively, we have

$$T[ax_1 + bx_2] = aT[x_1] + bT[x_2] = ay_1 + by_2 \quad (2.5)$$

In the following, only linear, time-invariant filters will be considered, even if several interesting applications of nonlinear [Glaser and Ruchkin, 1976; Tompkins, 1993] or time-variant [Huta and Webster, 1973; Widrow et al., 1975; Cohen, 1983; Thakor, 1987] filters have been proposed in the literature for the analysis of biologic signals.

The behavior of a filter is usually described in terms of input–output relationships. They are usually assessed by exciting the filter with different inputs and evaluating which is the response (output) of the system. In particular, if the input is the impulse sequence  $\delta(n)$ , the resulting output, the impulse response, has a relevant role in describing the characteristic of the filter. Such a response can be used to determine the response to more complicated input sequences. In fact, let us consider a generic input sequence  $x(n)$  as a sum of weighted and delayed impulses.

$$x(n) = \sum_{k=-\infty, \infty} x(k) \cdot \delta(n - k) \quad (2.6)$$

and let us identify the response to  $\delta(n - k)$  as  $h(n - k)$ . If the filter is time-invariant, each delayed impulse will produce the same response, but time-shifted; due to the linearity property, such responses will be

**FIGURE 2.5** General block diagram of a digital filter. The output digital signal  $y(n)$  is obtained from the input  $x(n)$  by means of a transformation  $T[\cdot]$  which identifies the filter.

summed at the output:

$$y(n) = \sum_{k=-\infty, \infty} x(k) \cdot h(n - k) \tag{2.7}$$

This convolution product links input and output and defines the property of the filter. Two of them should be recalled: *stability* and *causality*. The former ensures that bounded (finite) inputs will produce bounded outputs. Such a property can be deduced by the impulse response; it can be proved that the filter is stable if and only if

$$\sum_{k=-\infty, \infty} |h(k)| < \infty \tag{2.8}$$

*Causality* means that the filter will not respond to an input before the input is applied. This is in agreement with our physical concept of a system, but it is not strictly required for a digital filter that can be implemented in a noncausal form. A filter is causal if and only if

$$h(k) = 0 \quad \text{for } k < 0 \tag{2.8a}$$

Even if Equation 2.7 completely describes the properties of the filter, most often it is necessary to express the input–output relationships of linear discrete-time systems under the form of the *z*-transform operator, which allows one to express Equation 2.7 in a more useful, operative, and simpler form.

### 2.2.1.1 The *z*-Transform

The *z*-transform of a sequence  $x(n)$  is defined by [Rainer et al., 1972]

$$X(z) = \sum_{k=-\infty, \infty} x(k) \cdot z^{-k} \tag{2.9}$$

where  $z$  is a complex variable. This series will converge or diverge for different  $z$  values. The set of  $z$  values which makes Equation 2.9 converge is the **region of convergence**, and it depends on the series  $x(n)$  considered.

Among the properties of the *z*-transform, we recall

- The delay (shift) property:

$$\text{If } w(n) = x(n - T) \text{ then } W(z) = X(z) \cdot z^{-T} \tag{2.9a}$$

- The product of convolution:

$$\text{If } w(n) = \sum_{k=-\infty, \infty} x(k) \cdot y(n - k) \text{ then } W(z) = X(z) \cdot Y(z) \tag{2.9b}$$

### 2.2.1.2 The Transfer Function in the *z*-Domain

Thanks to the previous property, we can express Equation 2.7 in the *z*-domain as a simple multiplication:

$$Y(z) = H(z) \cdot X(z) \tag{2.10}$$

where  $H(z)$ , known as *transfer function* of the filter, is the *z*-transform of the impulse response.  $H(z)$  plays a relevant role in the analysis and design of digital filters. The response to input sinusoids can be

**FIGURE 2.6** Modulus (a) and phase (b) diagrams of the frequency response of a moving average filter of order 5. Note that the frequency plots are depicted up to  $\pi$ . In fact, taking into account that we are dealing with a sampled signal whose frequency information is up to  $f_s/2$ , we have  $\omega_{\max} = 2\pi f_s/2 = \pi f_s$  or  $\omega_{\max} = \pi$  if normalized with respect to the sampling rate.

evaluated as follows: assume a complex sinusoid  $x(n) = e^{j\omega n T_s}$  as input, the correspondent filter output will be

$$y(n) = \sum_{k=0, \infty} h(k)e^{j\omega T_s(n-k)} = e^{-j\omega n T_s} \sum_{k=0, \infty} h(k)e^{-j\omega k T_s} = x(n) \cdot H(z)|_{z=e^{j\omega T_s}} \quad (2.11)$$

Then a sinusoid in input is still the same sinusoid at the output, but multiplied by a complex quantity  $H(\omega)$ . Such complex function defines the response of the filter for each sinusoid of  $\omega$  pulse in input, and it is known as the frequency response of the filter. It is evaluated in the complex  $z$  plane by computing  $H(z)$  for  $z = e^{j\omega n T_s}$ , namely, on the point locus that describes the unitary circle on the  $z$  plane ( $|e^{j\omega n T_s}| = 1$ ). As a complex function,  $H(\omega)$  will be defined by its module  $|H(\omega)|$  and by its phase  $\angle H(\omega)$  functions, as shown in Figure 2.6 for a moving average filter of order 5. The figure indicates that the lower-frequency components will come through the filter almost unaffected, while the higher-frequency components will be drastically reduced. It is usual to express the horizontal axis of frequency response from 0 to  $\pi$ . This is obtained because only pulse frequencies up to  $\omega_s/2$  are reconstructable (due to the Shannon theorem), and therefore, in the horizontal axis, the value of  $\omega T_s$  is reported which goes from 0 to  $\pi$ . Furthermore, Figure 2.6b demonstrates that the phase is piecewise linear, and in correspondence with the zeros of  $|H(\omega)|$ , there is a change in phase of  $\pi$  value. According to their frequency response, the filters are usually classified as (1) low-pass, (2) high-pass, (3) bandpass, or (4) bandstop filters. Figure 2.7 shows the ideal frequency response for such filters with the proper low- and high-frequency cutoffs.

For a large class of linear, time-invariant systems,  $H(z)$  can be expressed in the following general form:

$$H(z) = \frac{\sum_{m=0, M} b_m z^{-m}}{1 + \sum_{k=1, N} a_k z^{-k}} \quad (2.12)$$

which describes in the  $z$  domain the following *difference equation* in this discrete time domain:

$$y(n) = - \sum_{k=1, N} a_k y(n - k) + \sum_{m=0, M} b_m x(n - m) \quad (2.13)$$

When at least one of the  $a_k$  coefficients is different from zero, some output values contribute to the current output. The filter contains some feedback, and it is said to be implemented in a recursive form. On the other hand, when the  $a_k$  values are all zero, the filter output is obtained only from the current or previous inputs, and the filter is said to be implemented in a *nonrecursive* form.

FIGURE 2.7 Ideal frequency-response moduli for low-pass (a), high-pass (b), bandpass (c), and bandstop filters (d).

The transfer function can be expressed in a more useful form by finding the roots of both numerator and denominator:

$$H(z) = \frac{b_0 z^{N-M} \prod_{m=1,M} (z - z_m)}{\prod_{k=1,N} (z - P_k)} \tag{2.14}$$

where  $z_m$  are the zeroes and  $p_k$  are the poles. It is worth noting that  $H(z)$  presents  $N - M$  zeros in correspondence with the origin of the  $z$  plane and  $M$  zeroes elsewhere ( $N$  zeroes totally) and  $N$  poles. The pole-zero form of  $H(z)$  is of great interest because several properties of the filter are immediately available from the geometry of poles and zeroes in the complex  $z$  plane. In fact, it is possible to easily assess stability and by visual inspection to roughly estimate the frequency response without making any calculations.

Stability is verified when all poles lie inside the unitary circle, as can be proved by considering the relationships between the  $z$ -transform and the Laplace  $s$ -transform and by observing that the left side of the  $s$  plane is mapped inside the unitary circle [Jackson, 1986; Oppenheim and Schaffer, 1975].

The frequency response can be estimated by noting that  $(z - z_m)|_{z=e^{j\omega n T_s}}$  is a vector joining the  $m$ th zero with the point on the unitary circle identified by the angle  $\omega T_s$ . Defining

$$\begin{aligned} \vec{B}_m &= (z - z_m)|_{z=e^{j\omega T_s}} \\ \vec{A}_k &= (z - p_k)|_{z=e^{j\omega T_s}} \end{aligned} \tag{2.15}$$

we obtain

$$\begin{aligned} |H(\omega)| &= \frac{b_0 \prod_{m=1,M} |\vec{B}_m|}{\prod_{k=1,N} |\vec{A}_k|} \\ \angle H(\omega) &= \sum_{m=1,M} \angle \vec{B}_m - \sum_{k=1,N} \angle \vec{A}_k + (N - M)\omega T_s \end{aligned} \tag{2.16}$$

Thus the modulus of  $H(\omega)$  can be evaluated at any frequency  $\omega^\circ$  by computing the distances between poles and zeroes and the point on the unitary circle corresponding to  $\omega = \omega^\circ$ , as evidenced in Figure 2.8, where a filter with two pairs of complex poles and three zeroes is considered.

**FIGURE 2.8** Poles and zeroes geometry (a) and relative frequency response modulus (b) and phase (c) characteristics. Moving around the unitary circle a rough estimation of  $|H(\omega)|$  and  $\angle H(\omega)$  can be obtained. Note the zeroes' effects at  $\pi$  and  $\pi/2$  and modulus rising in proximity of the poles. Phase shifts are clearly evident in part c closer to zeroes and poles.

To obtain the estimate of  $H(\omega)$ , we move around the unitary circle and roughly evaluate the effect of poles and zeroes by keeping in mind a few rules [Challis and Kitney, 1982] (1) when we are close to a zero,  $|H(\omega)|$  will approach zero, and a positive phase shift will appear in  $\angle H(\omega)$  as the vector from the zero reverses its angle; (2) when we are close to a pole,  $|H(\omega)|$  will tend to peak, and a negative phase change is found in  $\angle H(\omega)$  (the closer the pole to unitary circle, the sharper is the peak until it reaches infinite and the filter becomes unstable); and (3) near a closer pole-zero pair, the response modulus will tend to zero or infinity if the zero or the pole is closer, while far from this pair, the modulus can be considered unitary. As an example, it is possible to compare the modulus and phase diagram of Figure 2.8b,c with the relative geometry of the poles and zeroes of Figure 2.8a.

**2.2.1.3 FIR and IIR Filters**

A common way of classifying digital filters is based on the characteristics of their impulse response. For finite impulse response (FIR) filters,  $h(n)$  is composed of a finite number of nonzero values, while for infinite impulse response (IIR) filters,  $h(n)$  oscillates up to infinity with nonzero values. It is clearly evident that in order to obtain an infinite response to an impulse in input, the IIR filter must contain some feedback that sustains the output as the input vanishes. The presence of feedback paths requires putting particular attention to the filter stability.

Even if FIR filters are usually implemented in a nonrecursive form and IIR filters in a recursive form, the two ways of classification are not coincident. In fact, as shown by the following example, a FIR filter can be expressed in a recursive form:

$$H(z) = \sum_{k=0, N-1} z^{-k} = \sum_{k=0, N-1} z^{-k} \frac{(1 - z^{-1})}{(1 - z^{-1})} = \frac{1 - z^{-N}}{1 - z^{-1}} \tag{2.17}$$

for a more convenient computational implementation.

As shown previously, two important requirements for filters are stability and linear phase response. FIR filters can be easily designed to fulfill such requirements; they are always stable (having no poles outside the origin), and the linear phase response is obtained by constraining the impulse response coefficients to have symmetry around their midpoint. Such constrain implies

$$b_m = \pm b_{M-m}^* \tag{2.18}$$

where the  $b_m$  are the  $M$  coefficients of an FIR filter. The sign  $+$  or  $-$  stays in accordance with the symmetry (even or odd) and  $M$  value (even or odd). This is a necessary and sufficient condition for FIR filters to have linear phase response. Two cases of impulse response that yield a linear phase filter are shown in Figure 2.9.

FIGURE 2.9 Examples of impulse response for linear phase FIR filters: odd (a) and even (b) number of coefficients.

FIGURE 2.10 Amplitude response for a real low-pass filter. Ripples are admitted in both passband and stopband, but they are constrained into restricted areas. Limitations are also imposed to the width of the transition band.

It should be noted that Equation 2.18 imposes geometric constraints to the zero locus of  $H(z)$ . Taking into account Equation 2.12, we have

$$z^M H(z) = H\left(\frac{1}{z^*}\right) \tag{2.19}$$

Thus, both  $z_m$  and  $1/z_m^*$  must be zeroes of  $H(z)$ . Then the zeroes of linear phase FIR filters must lie on the unitary circle, or they must appear in pairs and with inverse moduli.

### 2.2.1.4 Design Criteria

In many cases, the filter is designed in order to satisfy some requirements, usually on the frequency response, which depend on the characteristic of the particular application the filter is intended for. It is known that ideal filters, like those reported in Figure 2.7, are not physically realizable (they would require an infinite number of coefficients of impulse response); thus we can design FIR or IIR filters that can only mimic, with an acceptable error, the ideal response. Figure 2.10 shows a frequency response of a not ideal low-pass filter. Here, there are ripples in passband and in stopband, and there is a transition band from passband to stopband, defined by the interval  $\omega_s - \omega_p$ .

Several design techniques are available, and some of them require heavy computational tasks, which are capable of developing filters with defined specific requirements. They include window technique, frequency-sampling method, or equiripple design for FIR filters. Butterworth, Chebychev, elliptical design, and impulse-invariant or bilinear transformation are instead employed for IIR filters. For detailed analysis of digital filter techniques, see Antoniou [1979], Cerutti [1983], and Oppenheim and Schaffer [1975].

### 2.2.1.5 Examples

A few examples of different kinds of filters will be presented in the following, showing some applications on ECG signal processing. It is shown that the ECG contains relevant information over a wide range of frequencies; the lower-frequency contents should be preserved for correct measurement of the slow ST displacements, while higher-frequency contents are needed to correctly estimate amplitude and duration of the faster contributions, mainly at the level of the QRS complex. Unfortunately, several sources of noise are present in the same frequency band, such as, higher-frequency noise due to muscle contraction (EMG noise), the lower-frequency noise due to motion artifacts (baseline wandering), the effect of respiration or the low-frequency noise in the skin-electrode interface, and others.

In the first example, the effect of two different low-pass filters will be considered. An ECG signal corrupted by an EMG noise (Figure 2.11a) is low-pass filtered by two different low-pass filters whose frequency responses are shown in Figure 2.11b,c. The two FIR filters have cutoff frequencies at 40 and 20 Hz, respectively, and were designed through window techniques (Weber–Cappellini window, filter length = 256 points) [Cappellini et al., 1978].

The output signals are shown in Figure 2.11d,e. Filtering drastically reduces the superimposed noise but at the same time alters the original ECG waveform. In particular, the *R* wave amplitude is progressively reduced by decreasing the cutoff frequency, and the QRS width is progressively increased as well. On the other hand, *P* waves appear almost unaffected, having frequency components generally lower than 20 to 30 Hz. At this point, it is worth noting that an increase in QRS duration is generally associated with various pathologies, such as ventricular hypertrophy or bundle-branch block. It is therefore necessary to check that an excessive band limitation does not introduce a false-positive indication in the diagnosis of the ECG signal.

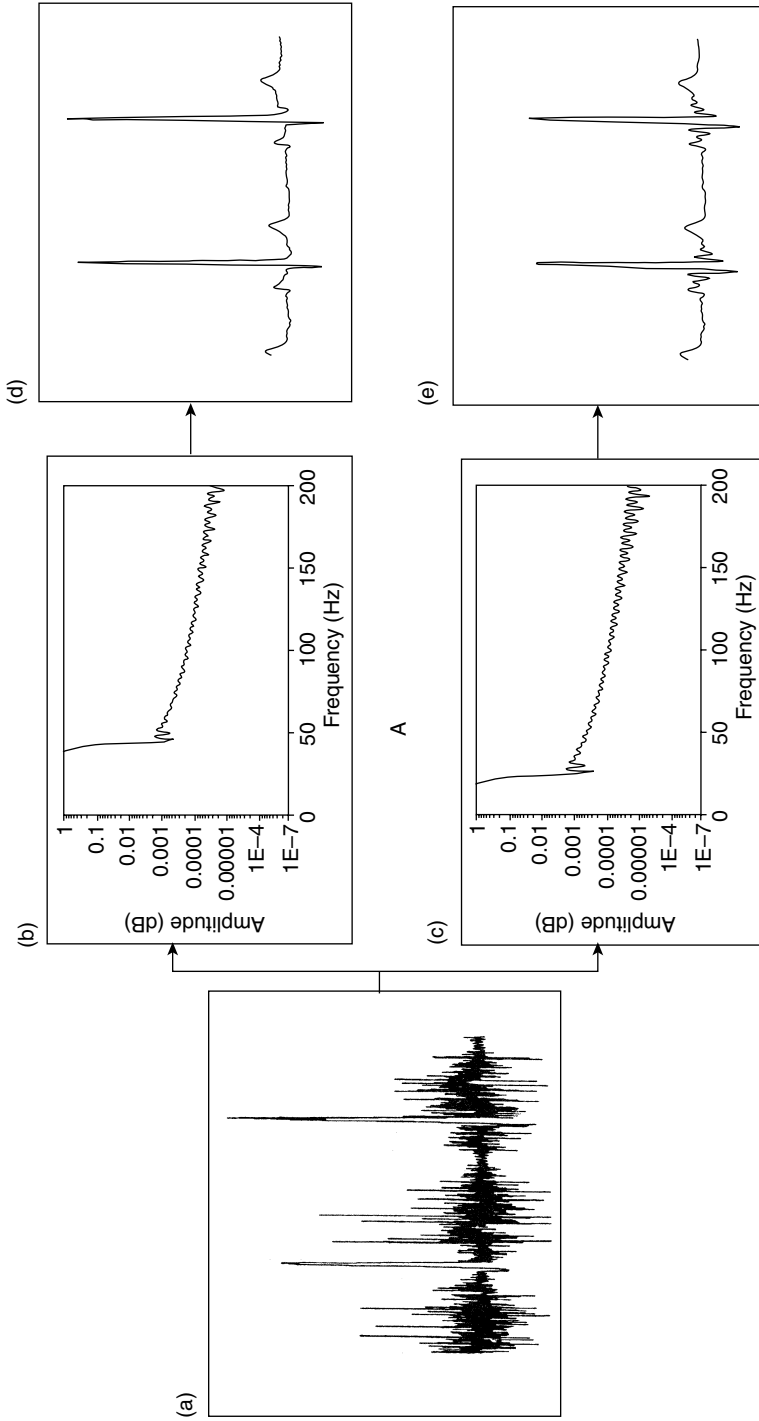

An example of an application for stopband filters (**notch filters**) is presented in Figure 2.12. It is used to reduce the 50-Hz mains noise on the ECG signal, and it was designed by placing a zero in correspondence of the frequency we want to suppress.

Finally, an example of a high-pass filter is shown for the detection of the QRS complex. Detecting the time occurrence of a fiducial point in the QRS complex is indeed the first task usually performed in ECG signal analysis. The QRS complex usually contains the higher-frequency components with respect to the other ECG waves, and thus such components will be enhanced by a high-pass filter. Figure 2.13 shows how QRS complexes (Figure 2.13a) can be identified by a derivative high-pass filter with a cutoff frequency to decrease the effect of the noise contributions at high frequencies (Figure 2.13b). The filtered signal (Figure 2.13c) presents sharp and well-defined peaks that are easily recognized by a threshold value.

## 2.2.2 Signal Averaging

Traditional filtering performs very well when the frequency content of signal and noise do not overlap. When the noise bandwidth is completely separated from the signal bandwidth, the noise can be decreased easily by means of a linear filter according to the procedures described earlier. On the other hand, when the signal and noise bandwidth overlap and the noise amplitude is enough to seriously corrupt the signal, a traditional filter, designed to cancel the noise, also will introduce signal cancellation or, at least, distortion. As an example, let us consider the brain potentials evoked by a sensory stimulation (visual, acoustic, or somatosensory) generally called evoked potentials (EP). Such a response is very difficult to determine because its amplitude is generally much lower than the background EEG activity. Both EP and EEG signals contain information in the same frequency range; thus the problem of separating the desired response cannot be approached via traditional digital filtering [Aunon et al., 1981]. Another typical example is in the detection of ventricular late potentials (VLP) in the ECG signal. These potentials are very small in amplitude and are comparable with the noise superimposed on the signal and also for what concerns the frequency content [Simson, 1981]. In such cases, an increase in the SNR may be achieved on the basis of different statistical properties of signal and noise.

When the desired signal repeats identically at each iteration (i.e., the EP at each sensory stimulus, the VLP at each cardiac cycle), the averaging technique can satisfactorily solve the problem of separating signal

**FIGURE 2.11** Effects of two different low-pass filters (b) and (c) on an ECG trace (a) corrupted by EMG noise. Both amplitude reduction and variation in the QRS induced by too drastic low-pass filtering are evidenced.

FIGURE 2.12 A 50-Hz noisy ECG signal (a); a 50-Hz rejection filter (b); and a filtered signal (c).

FIGURE 2.13 Effect of a derivative high-pass filter (b) on an ECG lead (a). The output of the filter (c).

from noise. This technique sums a set of temporal epochs of the signal together with the superimposed noise. If the time epochs are properly aligned, through efficient trigger-point recognition, the signal waveforms directly sum together. If the signal and the noise are characterized by the following statistical properties:

1. All the signal epochs contain a deterministic signal component  $x(n)$  that does not vary for all the epochs.

2. The superimposed noise  $w(n)$  is a broadband stationary process with zero mean and variance  $\sigma^2$  so that

$$\begin{aligned} E[w(n)] &= 0 \\ E[w^2(n)] &= \sigma^2 \end{aligned} \quad (2.20)$$

3. Signal  $x(n)$  and noise  $w_i(n)$  are uncorrelated so that the recorded signal  $y(n)$  at the  $i$ th iteration can be expressed as

$$y(n)_i = x(n) + w_i(n) \quad (2.21)$$

Then the averaging process yields  $y_t$ :

$$y_t(n) = \frac{1}{N} \sum_{i=1}^N y_i = x(n) + \sum_{i=1}^N w_i(n) \quad (2.22)$$

The noise term is an estimate of the mean by taking the average of  $N$  realizations. Such an average is a new random variable that has the same mean of the sum terms (zero in this case) and which has variance of  $\sigma^2/N$ . The effect of the coherent averaging procedure is then to maintain the amplitude of the signal and reduce the variance of the noise by a factor of  $N$ . In order to evaluate the improvement in the SNR (in rms value) in respect to the SNR (at the generic  $i$ th sweep):

$$\text{SNR} = \text{SNR}_i \cdot \sqrt{N} \quad (2.23)$$

Thus signal averaging improves the SNR by a factor of in rms value.

A coherent averaging procedure can be viewed as a digital filtering process, and its frequency characteristics can be investigated. From Equation 2.17 through the  $z$ -transform, the transfer function of the filtering operation results in

$$H(z) = \frac{1 + z^{-h} + z^{-2h} + \dots + L + z^{-(N-1)h}}{N} \quad (2.24)$$

where  $N$  is the number of elements in the average, and  $h$  is the number of samples in each response. An alternative expression for  $H(z)$  is

$$H(z) = \frac{1}{N} \frac{1 - z^{Nh}}{1 - z^h} \quad (2.25)$$

This is a moving average low-pass filter as discussed earlier, where the output is a function of the preceding value with a lag of  $h$  samples; in practice, the filter operates not on the time sequence but in the sweep sequence on corresponding samples.

The frequency response of the filter is shown in Figure 2.14 for different values of the parameter  $N$ . In this case, the sampling frequency  $f_s$  is the repetition frequency of the sweeps, and we may assume it to be 1 without loss of generality. The frequency response is characterized by a main lobe with the first zero corresponding to  $f = 1/N$  and by successive secondary lobes separated by zeroes at intervals  $1/N$ . The width of each tooth decreases as well as the amplitude of the secondary lobes when increasing the number  $N$  of sweeps.

The desired signal is sweep-invariant, and it will be unaffected by the filter, while the broadband noise will be decreased. Some leakage of noise energy takes place in the center of the sidelobes and, of course, at zero frequency. Under the hypothesis of zero mean noise, the dc component has no effect, and the

FIGURE 2.14 Equivalent frequency response for the signal-averaging procedure for different values of  $N$  (see text).

diminishing sidelobe amplitude implies the leakage to be not relevant for high frequencies. It is important to recall that the average filtering is based on the hypothesis of broadband distribution of the noise and lack of correlation between signal and noise. Unfortunately, these assumptions are not always verified in biological signals. For example, the assumptions of independence of the background EEG and the evoked potential may be not completely realistic [Gevins and Remond, 1987]. In addition, much attention must be paid to the alignment of the sweeps; in fact, slight misalignments (fiducial point jitter) will lead to a low-pass filtering effect of the final result.

**2.2.2.1 Example**

As mentioned previously, one of the fields in which signal-averaging technique is employed extensively is in the evaluation of cerebral evoked response after a sensory stimulation. Figure 2.15a shows the EEG recorded from the scalp of a normal subject after a somatosensory stimulation released at time  $t = 0$ . The evoked potential ( $N = 1$ ) is not visible because it is buried in the background EEG (upper panel). In the successive panels there is the same evoked potential after averaging different numbers of sweeps corresponding to the frequency responses shown in Figure 2.14. As  $N$  increases, the SNR is improved by a factor  $\sqrt{N}$  (in rms value), and the morphology of the evoked potential becomes more recognizable while the EEG contribution is markedly diminished. In this way it is easy to evaluate the quantitative indices of clinical interest, such as the amplitude and the latency of the relevant waves.

**FIGURE 2.15** Enhancement of evoked potential (EP) by means of averaging technique. The EEG noise is progressively reduced, and the EP morphology becomes more recognizable as the number of averaged sweeps ( $N$ ) is increased.

### 2.2.3 Spectral Analysis

The various methods to estimate the power spectrum density (PSD) of a signal may be classified as *nonparametric* and *parametric*.

#### 2.2.3.1 Nonparametric Estimators of PSD

This is a traditional method of frequency analysis based on the Fourier transform that can be evaluated easily through the fast Fourier transform (FFT) algorithm [Marple, 1987]. The expression of the PSD as a function of the frequency  $P(f)$  can be obtained directly from the time series  $y(n)$  by using the periodogram

expression

$$P(f) = \frac{1}{T_s} \left| T_s \sum_{k=0}^{N-1} y(k) e^{-j2\pi f k T_s} \right|^2 = \frac{1}{N T_s} |Y(f)|^2 \quad (2.26)$$

where  $T_s$  is the sampling period,  $N$  is the number of samples, and  $Y(f)$  is the discrete time Fourier transform of  $y(n)$ .

On the basis of the Wiener–Khinchin theorem, PSD is also obtainable in two steps from the FFT of the autocorrelation function  $\hat{R}_{yy}(k)$  of the signal, where  $\hat{R}_{yy}(k)$  is estimated by means of the following expression:

$$\hat{R}_{yy}(k) = \frac{1}{N} \sum_{i=0}^{N-k-1} y(i) y^*(i+k) \quad (2.27)$$

where  $*$  denotes the complex conjugate. Thus the PSD is expressed as

$$P(f) = T_s \cdot \sum_{k=-N}^N \hat{R}_{yy}(k) e^{-j2\pi f k T_s} \quad (2.28)$$

based on the available lag estimates  $\hat{R}_{yy}(k)$ , where  $-(1/2T_s) \leq f \leq (1/2T_s)$ .

FFT-based methods are widely diffused, for their easy applicability, computational speed, and direct interpretation of the results. Quantitative parameters are obtained by evaluating the power contribution at different frequency bands. This is achieved by dividing the frequency axis in ranges of interest and by integrating the PSD on such intervals. The area under this portion of the spectrum is the fraction of the total signal variance due to the specific frequencies. However, autocorrelation function and Fourier transform are theoretically defined on infinite data sequences. Thus errors are introduced by the need to operate on finite data records in order to obtain estimators of the true functions. In addition, for the finite data set it is necessary to make assumptions, sometimes not realistic, about the data outside the recording window; commonly they are considered to be zero. This implicit rectangular windowing of the data results in a special leakage in the PSD. Different windows that smoothly connect the side samples to zero are most often used in order to solve this problem, even if they may introduce a reduction in the frequency resolution [Harris, 1978]. Furthermore, the estimators of the signal PSD are not statistically consistent, and various techniques are needed to improve their statistical performances. Various methods are mentioned in the literature; the methods of Dariell [1946], Bartlett [1948], and Welch [1970] are the most diffused ones. Of course, all these procedures cause a further reduction in frequency resolution.

### 2.2.3.2 Parametric Estimators

Parametric approaches assume the time series under analysis to be the output of a given mathematical model, and no drastic assumptions are made about the data outside the recording window. The PSD is calculated as a function of the model parameters according to appropriate expressions. A critical point in this approach is the choice of an adequate model to represent the data sequence. The model is completely independent of the physiologic, anatomic, and physical characteristics of the biologic system but provides simply the input–output relationships of the process in the so-called black-box approach.

Among the numerous possibilities of modeling, linear models, characterized by a rational transfer function, are able to describe a wide number of different processes. In the most general case, they are represented by the following linear equation that relates the input-driving signal  $w(k)$  and the output of

an autoregressive moving average (ARMA) process:

$$y(k) = - \sum_{i=1}^p a_i y(k - i) + \sum_{j=1}^q b_j w(k - j) + w(k) \tag{2.29}$$

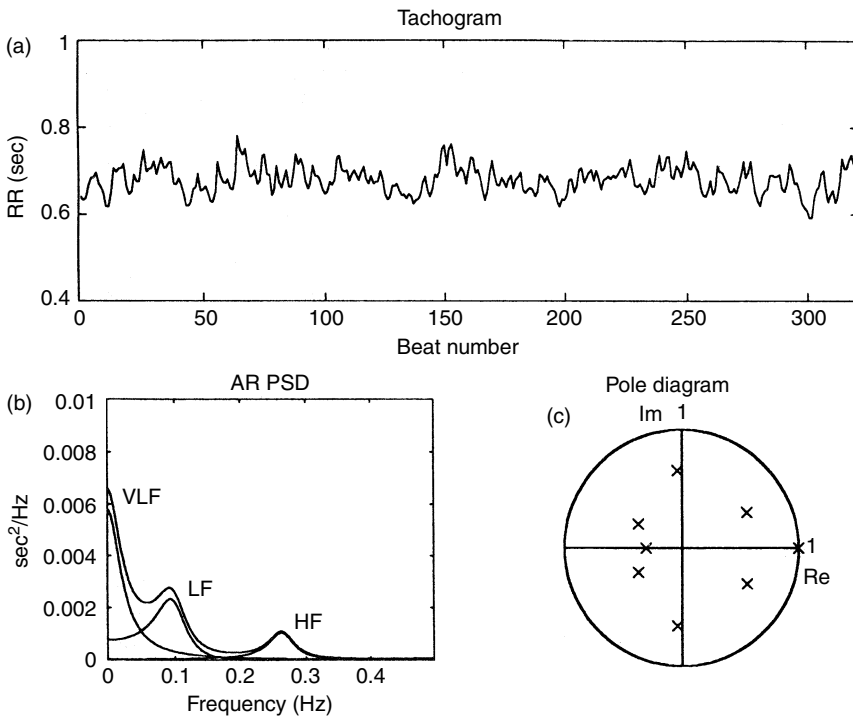

where  $w(k)$  is the input white noise with zero mean value and variance  $\lambda^2$ ,  $p$  and  $q$  are the orders of AR and MA parts, respectively, and  $a_i$  and  $b_j$  are the proper coefficients.

The ARMA model may be reformulated as an AR or an MA if the coefficients  $b_j$  or  $a_i$  are, respectively, set to zero. Since the estimation of the AR parameters results in liner equations, AR models are usually employed in place of ARMA or MA models, also on the basis of the Wold decomposition theorem [Marple, 1987] that establishes that any stationary ARMA or MA process of finite variance can be represented as a unique AR model of appropriate order, even infinite; likewise, any ARMA or AR process can be represented by an MA model of sufficiently high order.

The AR PSD is then obtained from the following expression:

$$P(f) = \frac{\lambda^2 T_s}{|1 + \sum_{i=1}^p a_i z^{-i}|^2}_{z=\exp(j2\pi f T_s)} = \frac{\lambda^2 T_s}{\prod_{i=1}^p (z - z_i)^2}_{z=\exp(j2\pi f T_s)} \tag{2.30}$$

The right side of the relation puts into evidence the poles of the transfer function that can be plotted in the  $z$ -transform plane. Figure 2.16b shows the PSD function of the HRV signal depicted in Figure 2.16a, while Figure 2.16c displays the corresponding pole diagram obtained according to the procedure described in the preceding section.

**FIGURE 2.16** (a) Interval tachogram obtained from an ECG recording as the sequence of the RR time intervals expressed in seconds as a function of the beat number. (b) PSD of the signal (a) evaluated by means of an AR model (see text). (c) Pole diagram of the PSD shown in (b).

**Parametric methods** are methodologically and computationally more complex than the nonparametric ones, since they require an a priori choice of the structure and of the order of the model of the signal-generation mechanism. Some tests are required a posteriori to verify the whiteness of the prediction error, such as the Anderson test (autocorrelation test) [Box and Jenkins, 1976] in order to test the reliability of the estimation.

Postprocessing of the spectra can be performed as well as for nonparametric approaches by integrating the  $P(f)$  function in predefined frequency ranges; however, the AR modeling has the advantage of allowing a spectral decomposition for a direct and automatic calculation of the power and frequency of each spectral component. In the  $z$ -transform domain, the autocorrelation function (ACF)  $R(k)$  and the  $P(z)$  of the signal are related by the following expression:

$$R(k) = \frac{1}{2\pi j} \int_{|z|=1} P(z)z^{k-1} dz \quad (2.31)$$

If the integral is calculated by means of the residual method, the ACF is decomposed into a sum of damped sinusoids, each one related to a pair of complex conjugate poles, and of damped exponential functions, related to the real poles [Zetterberg, 1969]. The Fourier transform of each one of these terms gives the expression of each spectral component that fits the component related to the relevant pole or pole pair. The argument of the pole gives the central frequency of the component, while the  $i$ th spectral component power is the residual  $\gamma_i$  in the case of real poles and  $2\text{Re}(\gamma_i)$  in case of conjugate pole pairs.  $\gamma_i$  is computed from the following expression:

$$\gamma_i = z^{-1}(z - z_i)P(z)|_{z=z_i}$$

It is advisable to point out the basic characteristics of the two approaches that have been described above: the nonparametric and the parametric. The latter (parametric) has evident advantages with respect to the former, which can be summarized in the following:

- It has a more statistical consistency even on short segments of data; that is, under certain assumptions, a spectrum estimated through autoregressive modeling is a maximum entropy spectrum (MES).
- The spectrum is more easily interpretable with an “implicit” filtering of what is considered random noise.
- An easy and more reliable calculation of the spectral parameters (postprocessing of the spectrum), through the spectral decomposition procedure, is possible. Such parameters are directly interpretable from a physiologic point of view.
- There is no need to window the data in order to decrease the spectral leakage.
- The frequency resolution does not depend on the number of data.

On the other hand, the parametric approach

- Is more complex from a methodologic and computational point of view.
- Requires an a priori definition of the kind of model (AR, MA, ARMA, or other) to be fitted and mainly its complexity defined (i.e., the number of parameters).

Some figures of merit introduced in the literature may be of help in determining their value [Akaike, 1974]. Still, this procedure may be difficult in some cases.

### 2.2.3.3 Example

As an example, let us consider the frequency analysis of the heart rate variability (HRV) signal. In Figure 2.16a, the time sequence of the RR intervals obtained from an ECG recording is shown. The RR intervals are expressed in seconds as a function of the beat number in the so-called interval tachogram. It is worth noting that the RR series is not constant but is characterized by oscillations of up to the 10% of

its mean value. These oscillations are not causal but are the effect of the action of the autonomic nervous system in controlling heart rate. In particular, the frequency analysis of such a signal (Figure 2.16b shows the PSD obtained by means of an AR model) has evidenced three principal contributions in the overall variability of the HRV signal. A very low frequency (VLF) component is due to the long-term regulation mechanisms that cannot be resolved by analyzing a few minutes of signal (3 to 5 min are generally studied in the traditional spectral analysis of the HRV signal). Other techniques are needed for a complete understanding of such mechanisms. The low-frequency (LF) component is centered around 0.1 Hz, in a range between 0.03 and 0.15 Hz. An increase in its power has always been observed in relation to sympathetic activations. Finally, the high-frequency (HF) component, in synchrony with the respiration rate, is due to the respiration activity mediated by the vagus nerve; thus it can be a marker of vagal activity. In particular, LF and HF power, both in absolute and in normalized units (i.e., as percentage value on the total power without the VLF contribution), and their ratio LF/HF are quantitative indices widely employed for the quantification of the sympathovagal balance in controlling heart rate [Malliani et al., 1991].

## 2.3 Conclusion

---

The basic aspects of signal acquisition and processing have been illustrated, intended as fundamental tools for the treatment of biologic signals. A few examples also were reported relative to the ECG signal, as well as EEG signals and EPs. Particular processing algorithms have been described that use digital filtering techniques, coherent averaging, and power spectrum analysis as reference examples on how traditional or innovative techniques of digital signal processing may impact the phase of informative parameter extraction from biologic signals. They may improve the knowledge of many physiologic systems as well as help clinicians in dealing with new quantitative parameters that could better discriminate between normal and pathologic cases.

### Defining Terms

**Aliasing:** Phenomenon that takes place when, in A/D conversion, the sampling frequency  $f_s$  is lower than twice the frequency content  $f_b$  of the signal; frequency components above  $f_s/2$  are folded back and are summed to the lower-frequency components, distorting the signal.

**Averaging:** Filtering technique based on the summation of  $N$  stationary waveforms buried in casual broadband noise. The SNR is improved by a factor of  $N$ .

**Frequency response:** A complex quantity that, multiplied by a sinusoid input of a linear filter, gives the output sinusoid. It completely characterizes the filter and is the Fourier transform of the impulse response.

**Impulse reaction:** Output of a digital filter when the input is the impulse sequence  $d(n)$ . It completely characterizes linear filters and is used for evaluating the output corresponding to different kinds of inputs.

**Notch filter:** A stopband filter whose stopped band is very sharp and narrow.

**Parametric methods:** Spectral estimation methods based on the identification of a signal generating model. The power spectral density is a function of the model parameters.

**Quantization error:** Error added to the signal, during the A/D procedure, due to the fact that the analog signal is represented by a digital signal that can assume only a limited and predefined set of values.

**Region of convergence:** In the  $z$ -transform plane, the ensemble containing the  $z$ -complex points that makes a series converge to a finite value.

### 3.1 Introduction

---

Computerized electrocardiogram (ECG), electroencephalogram (EEG), and magnetoencephalogram (MEG) processing systems have been widely used in clinical practice [1] and they are capable of recording and processing long records of biomedical signals. The use of such systems (1) enables the construction of large signal databases for subsequent evaluation and comparison, (2) makes the transmission of biomedical information feasible over telecommunication networks in real time or off line, and (3) increases the capabilities of ambulatory recording systems such as the Holter recorders for ECG signals. In spite of the great advances in VLSI memory technology, the amount of data generated by digital systems may become excessive quickly. For example, a Holter recorder needs more than 200 Mbits/day of memory space to store a dual-channel ECG signal sampled at a rate of 200 samples/sec with 10 bit/sample resolution. Since the recorded data samples are correlated with each other, there is an inherent redundancy in most biomedical signals. This can be exploited by the use of data compression techniques which have been successfully utilized in speech, image, and video signals [2] as well.

The aim of any biomedical signal compression scheme is to minimize the storage space without losing any clinically significant information, which can be achieved by eliminating redundancies in the signal, in a reasonable manner.

Data compression methods can be classified into two categories: (1) lossless and (2) lossy coding methods. In lossless data compression, the signal samples are considered to be realizations of a random variable or a random process and the entropy of the source signal determines the lowest compression ratio that can be achieved. In lossless coding the original signal can be perfectly reconstructed. For typical biomedical signals lossless (reversible) compression methods can only achieve Compression Ratios (CR) in the order of 2 to 1. On the other hand lossy (irreversible) techniques may produce CR results in the order of 10 to 1. In lossy methods, there is some kind of quantization of the input data which leads to higher CR results at the expense of reversibility. But this may be acceptable as long as no clinically significant degradation is introduced to the encoded signal. The CR levels of 2 to 1 are too low for most practical applications. Therefore, lossy coding methods which introduce small reconstruction errors are preferred in practice. In this section we review the lossy biomedical data compression methods.

## 3.2 Time-Domain Coding of Biomedical Signals

Biomedical signals can be compressed in time domain, frequency domain, or time–frequency domain. In this section the time domain techniques, which are the earlier approaches to biomedical signal compression, are reviewed.

### 3.2.1 Data Compression by DPCM

Differential pulse code modulation (DPCM) is a well-known data coding technique in which the main idea is to decorrelate the input signal samples by linear prediction. The current signal sample,  $x(n)$ , is estimated from the past samples by using either a fixed or adaptive linear predictor

$$\hat{x}(n) = \sum_{k=1}^N a_k x(n-k) \quad (3.1)$$

where  $\hat{x}(n)$  is the estimate of  $x(n)$  at discrete time instant  $n$ , and  $\{a_k\}$  is the predictor weight. The samples of the estimation error sequence,  $e(n) = x(n) - \hat{x}(n)$  are less correlated with each other compared to the original signal,  $x(n)$  as the predictor removes the unnecessary information which is the predictable portion of the sample  $x(n)$ . In a typical DPCM encoder, the error sequence is quantized by using a nonuniform quantizer and quantizer outputs are entropy coded by assigning variable-length codewords to the quantized error sequence according to the frequency of occurrence. The variable-length codebook is constructed by Huffman coding which assigns shorter (longer) codewords to values occurring with higher (lower) probabilities. Huffman coding produces compression results that are arbitrarily close to the entropy of the quantized error sequence.

A CR of 7.8 was reported for an ECG signal recorded at a rate of 500 Hz with 8 bit/sample resolution [3]. This means that about 1 bit/sample is used to represent the ECG signal. The corresponding percent root mean square difference (PRD) was 3.5. The PRD is a measure of reconstruction error and it is defined as follows:

$$\text{PRD} = \sqrt{\frac{\sum_{n=0}^{N-1} [x(n) - x_{\text{rec}}(n)]^2}{\sum_{n=0}^{N-1} x^2(n)}} * 100 \quad (3.2)$$

where  $N$  is the total number of samples in the ECG signal,  $x(n)$ , and  $x_{\text{rec}}(n)$  is the reconstructed ECG signal.

A typical DPCM encoder may become a lossless coder if the quantization step is skipped. In this case CR drops drastically to low values.

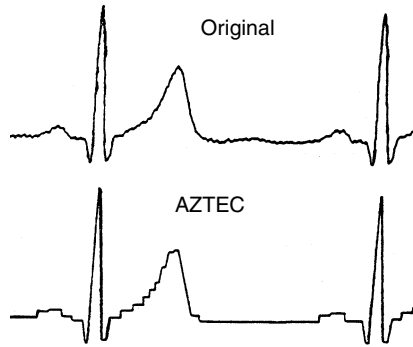

FIGURE 3.1 AZTEC representation of an ECG waveform.

### 3.2.2 AZTEC ECG Compression Method

The Amplitude Zone Time Epoch Coding (AZTEC) is one of the earliest ECG coding methods. It was developed by Cox et al. [4] as a preprocessing software for real-time monitoring of ECGs. It was observed to be useful for automatic analysis of ECGs such as QRS detection, but it is inadequate for visual presentation of the ECG signal as the reconstructed signal has a staircase appearance.

In this method the ECG signal is considered to consist of flat regions and “slopes.” If the signal value stays within a predetermined constant for more than three consecutive samples then that region is assumed to be constant and stored by its duration (number of samples) and a fixed amplitude value. Otherwise the signal is assumed to have a slope. A slope is stored by its duration and the amplitude of the last sample point. Linear interpolation is used to reconstruct the ECG signal. As a result, the resulting signal has a discontinuous nature as shown in Figure 3.1.

Even though AZTEC produces a high compression ratio ( $CR = 10$  to 1, for 500 Hz sampled data with 12 bit/sample resolution) the quality of the reconstructed signal is very low and it is not acceptable to the cardiologists.

Various modified of AZTEC are proposed [5]. One notable example is the CORTES technique [6]. The CORTES technique is a hybrid of the AZTEC and the Turning Point method which is described in the next section.

### 3.2.3 Turning Point ECG Compression Method

The Turning Point data reduction method [7] is basically an adaptive downsampling method developed especially for ECGs. It reduces the sampling frequency of an ECG signal by a factor of two.

The method is based on the trends of the signal samples. Three input samples are processed at a time. Let  $x(n)$  be the current sample at discrete-time instant  $n$ . Among the two consecutive input samples,  $x(n+1)$  and  $x(n+2)$ , the one producing the highest slope (in magnitude) is retained and the other sample is dropped. In this way the overall sampling rate is reduced to one-half of the original sampling rate; no other coding is carried out. Therefore, the resulting CR is 2 to 1. A PRD of 5.3% is reported for an ECG signal sampled at 200 Hz with 12 bit/sample resolution [7]. In practice the CR value actually may be lower than two as the retained samples may not be equally spaced and some extra bits may be needed for timing determination.

### 3.2.4 ECG Compression via Parameter Extraction

In these methods, the signal is analyzed and some important features such as typical cycles, extreme locations, etc. are determined. These features are properly stored. Reconstruction is carried out by using appropriate interpolation schemes.

The location of the extrema or peaks in an ECG signal is important in diagnosis because they basically determine the shape of each ECG period. The ECG compression techniques described in Reference 8 take advantage of this feature and record only the maxima, minima, slope changes, zero-crossing intervals, etc. of the signal. During reconstruction various interpolation schemes such as polynomial fitting and spline functions are used. The performance of the extrema based methods is compared to the AZTEC method and it was reported that for a given CR the RMS error is half of that of AZTEC method [8].

Other parameter extraction methods include [9,10] where ECG signals are analyzed in a cycle-synchronous manner. An AR model is fitted to the MEG signal and parameters of the AR model are stored [11]. An ECG signal is modeled by splines and the data is compressed by storing the spline parameters [12].

Review of some other time-domain ECG data compression methods can be found in Reference 5.

### 3.3 Frequency-Domain Data Compression Methods

Transform Coding (TC) is the most important frequency-domain digital waveform compression method [2]. The key is to divide the signal into frequency components and judiciously allocate bits in the frequency domain.

In most TC methods, the input signal is first divided into blocks of data and each block is linearly transformed into the “frequency” domain. Let  $x = [x_0, x_1, \dots, x_{N-1}]^T$  be a vector obtained from a block of  $N$  input samples. The transform domain coefficients,  $v_i, i = 0, 1, \dots, N - 1$ , are given by

$$v = Ax \quad (3.3)$$

where  $v = [v_0 v_1 \dots v_{N-1}]^T$ , and  $A$  is the  $N \times N$  transform matrix representing the linear transform. A variety of transform matrices including the discrete Fourier transform matrix is used in digital waveform coding [2]. In this section discrete Karhunen–Loeve Transform (KLT) and Discrete Cosine Transform (DCT), which are the most used ones, are reviewed.

If the input signal is a wide sense stationary random process then the so-called optimum linear transform, KLT is well defined and it decorrelates the entries of the input vector. This is equivalent to removing all the unnecessary information contained in the vector  $x$ . Therefore, by coding the entries of the  $v$  vector, only the useful information is retained. The entries of the  $v$  vector are quantized and stored. Usually, different quantizers are used to quantize the entries of the  $v$  vector. In general, more bits are allocated to those entries which have high energies compared to the ones with low energies.

The KLT is constructed from the eigenvectors of the autocovariance matrix of the input vector  $x$ . In most practical waveforms the statistics of the input vector change from block to block. Thus for each block a new KLT matrix must be constructed. This is computationally very expensive (in some practical cases a fixed KLT matrix is estimated and it is assumed to be constant for a reasonable amount of duration). Furthermore, there is no fast algorithm similar to the Fast Fourier Transform (FFT) to compute the KLT.

The Discrete Cosine Transform (DCT) [2] was developed by Ahmed et al., to approximate KLT when there is high correlation among the input samples, which is the case in many digital waveforms including speech, music, and biomedical signals.

The DCT  $v = [v_0, v_1, \dots, v_{N-1}]^T$  of the vector  $x$  is defined as follows:

$$v_0 = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} x_n \quad (3.4)$$

$$v_k = \sqrt{\frac{2}{N}} \sum_{n=0}^{N-1} x_n \cos \frac{(2n+1)k\pi}{2N} \quad k = 1, 2, \dots, (N-1) \quad (3.5)$$

where  $v_k$  is the  $k$ th DCT coefficient. The inverse discrete cosine transform (IDCT) of  $v$  is given as follows:

$$x_n = \frac{1}{\sqrt{N}}v_0 + \sqrt{\frac{2}{N}} \sum_{k=1}^{N-1} v_k \cos \frac{(2n+1)k\pi}{2N} \quad n = 0, 1, 2, \dots, (N-1) \quad (3.6)$$

$$\left( \frac{k\pi}{4}, \frac{(k+1)\pi}{4} \right)_{k=0,1,2,3} \quad (3.6a)$$

There exist fast algorithms, Order  $(N \log N)$ , to compute the DCT [2]. Thus, DCT can be implemented in a computationally efficient manner. Two recent image and video coding standards, JPEG and MPEG, use DCT as the main building block.

A CR of 3 to 1 for single channel ECG is reported by using DCT and KLT based coders [13]. For multi-lead systems, two-dimensional (2-D) transform based methods can be used. A CR of 12 to 1 was reported [14] for a three-lead system by using a 2-D KLT. Recently, Philips [15] developed a new transform by using time-warped polynomials and obtained a CR of 26 to 9. In this case a DCT based coding procedure produced a CR of 24 to 3.

Since signal recording conditions and noise levels vary from study to study, a thorough comparison of the coding methods is very difficult to make. But, frequency-domain coding methods produce higher coding results than time-domain coding methods.

### 3.4 Wavelet or Subband Coding

Wavelet Transform (WT) is a powerful time–frequency signal analysis tool and it is used in a wide variety of applications including signal and image coding [16]. WT and Subband Coding (SBC) are closely related to each other. In fact the fast implementation of WTs are carried out using Subband (SB) filter banks. Due to this reason WT based waveform coding methods are essentially similar to the SBC based methods.

In an SBC structure the basic building block is a digital filter bank which consists of a lowpass and a highpass filter. In the ideal case, the passband (stopband) of the lowpass filter is  $[0, \pi/2]$   $[\pi/2, \pi]$ . Let  $H_l(e^{j\omega})$   $H_u(e^{j\omega})$  be the frequency response of the lowpass (highpass) filter. In SBC the input signal which is sampled at the rate of  $f_s$  is filtered by  $H_l(e^{j\omega})$  and  $H_u(e^{j\omega})$  and the filter outputs are downsampled by a factor of two (every other sample is dropped) in order to maintain the overall sampling rate to be equal to the original rate. In this way two subsignals,  $x_i(n)$  and  $x_u(n)$  which both have a sampling rate of  $f_s/2$  are obtained. The block diagram of a two-level SBC structure is shown in Figure 3.1.

The subsignal,  $x_i(n)$  [ $x_u(n)$ ], contains the lowpass (highpass) frequency domain information of the original signal. The subsignals,  $x_i(n)$  and  $x_u(n)$ , can be further divided into their frequency components in a similar manner. This SB division process can be repeated until the frequency domain is divided in a sufficient manner. In Reference 17, the two-level subband structure of Figure 3.2 which divides the frequency domain into four regions, is used to code a single channel ECG signal. The resulting subsignals can be encoded by various coding methods including DPCM, Entropy coding, and transform coding which should be designed to exploit the special nature of the subsignals to achieve the best possible CR for each band. Recently, very successful special encoders which take advantage of the tree structure of the decomposition were developed for compressing the subsignals [18]. The signal reconstruction from the coded subsignals is carried out by using a filter bank consisting of two filters,  $G_l(e^{j\omega})$  and  $G_u(e^{j\omega})$ . In this case the subsignal,  $x_i(n)$  [ $x_u(n)$ ] is first upsampled by inserting a zero between every other sample and filtered by  $G_l(e^{j\omega})$  [ $G_u(e^{j\omega})$ ]. The reconstructed signal,  $y(n)$ , is the sum of the outputs of these two filters.

By properly selecting the filters,  $H_l(z)$ ,  $H_u(z)$ ,  $G_l(z)$ , and  $G_u(z)$ , perfect reconstruction is possible, that is,

$$y(n) = x(n - K) \quad (3.7)$$

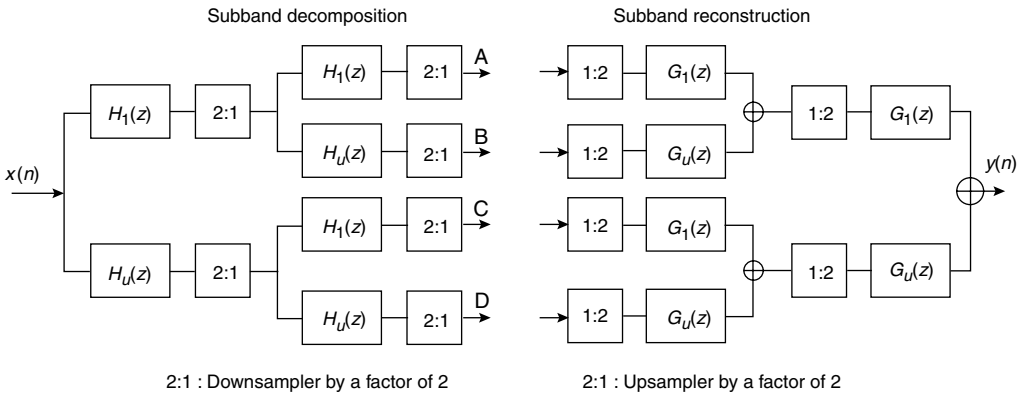

FIGURE 3.2 Two-level (four branch) subband coder structure. This structure divides the frequency domain into four regions.

FIGURE 3.3 Block diagram of the multichannel ECG data compression scheme.

in the absence of quantization errors [16]. In other words, filtering and downsampling operations in the SB decomposition structure do not introduce any loss.

A CR 5.22 corresponding to a PRD of 5.94% is reported for an ECG signal sampled at 500 Hz with 12 bit/sample resolution [17].

Other WT based ECG coding methods include [16,19–21].

### 3.5 Hybrid Multichannel ECG Coding

In this section, a hybrid frequency domain multichannel compression method [22] for the so-called standard lead [23] ECG recording system is described. The block diagram of this system is shown in Figure 3.3. The main idea is to exploit not only the correlation between the consecutive ECG samples, but also the inherent correlation among the ECG channels.

The standard lead system has 12 ECG channels. In this method, the recorded digital signals are first passed through a preprocessor. The function of the preprocessor is to prepare raw ECG data for further processing. After preprocessing the input signals, the resulting discrete-time sequences are linearly transformed into another set of sequences. The aim of this linear transformation is to decorrelate the highly correlated ECG lead signals. In a way, this idea is similar to representing the RGB color components of an image in terms of luminance and chrominance components.

The transformation matrix,  $A$ , can be the matrix of the optimum transform, KLT, or the DCT matrix. Another approach is to use a nonlinear transform such as an Independent Component Analyzer (ICA) [24]. Lastly, to compress the transform domain signals, various coding schemes which exploit their special nature are utilized.

In the following sections, detailed descriptions of the sub-blocks of the multichannel ECG compression method are given.

### 3.5.1 Preprocessor

The standard lead ECG recording configuration consists of 12 ECG leads, I, II, III, AVR, AVL, AVF, V1, V2, . . . , V6. The leads, III, AVR, AVL, and AVF, are linearly related to I and II. Therefore, eight channels are enough to represent a standard 12-channel ECG recording system.

The preprocessor discards the redundant channels, III, AVR, AVL, and AVF, and rearranges the order of the ECG channels. The six precordial (chest) leads, V1, . . . , V6, represent variations of the electrical heart vector amplitude with respect to time from six different narrow angles. During a cardiac cycle it is natural to expect high correlation among precordial leads so the channels V1, . . . , V6 are selected as the first 6 signals, that is,  $x_{i-1} = V_i, i = 1, 2, \dots, 6$ . The two horizontal lead waveforms (I and II) which have relatively less energy contents with respect to precordial ECG lead waveforms are chosen as seventh,  $x_6 = I$ , and eighth channels,  $x_7 = II$ . A typical set of standard ECG lead waveforms,  $x_i, i = 0, 1, \dots, 7$ , are shown in Figure 3.4.

The aim of the reordering the ECG channels is to increase the efficiency of the linear transformation operation which is described in the next section.

### 3.5.2 Linear Transformer

The outputs of the preprocessor block,  $x_i, i = 0, 1, \dots, 7$ , are fed to the linear transformer. In this block, the ECG channels are linearly transformed to another domain, and eight new transform domain signals  $y_i, i = 0, 1, \dots, 7$ , are obtained which are significantly less correlated (ideally uncorrelated) than the ECG signal set,  $x_i, i = 0, 1, \dots, 7$ . The transform domain samples at discrete-time instant  $m$  are given as follows:

$$Y_m = A \cdot X_m \tag{3.8}$$

where  $Y_m = [y_0(m), \dots, y_{N-1}(m)]T$ ,  $X_m = [x_0(m), \dots, x_{N-1}(m)]T$ , and  $A$  is the  $N \times N$  transform matrix.

The optimum linear transform, discrete KLT, can be properly defined for stationary random processes and the entries of the transform matrix,  $A_{KLT}$  depending on the statistics of the random processes. For slowly varying, unstationary signals, an approximate KLT matrix can also be defined. Although ECG signals cannot be considered to be wide-sense stationary-random processes, a covariance matrix,  $\hat{C}_x$ , of the ECG channels is estimated as follows:

$$\hat{C}_x = \frac{1}{M} \sum_{i=0}^{M-1} \begin{bmatrix} x_0(i) \\ \vdots \\ x_{N-1}(i) \end{bmatrix} [x_0(i) \cdots x_{N-1}(i)] \tag{3.9}$$

where  $N$  is the number of the ECG channels and  $M$  is the number of ECG samples per channel used. The  $N \times N$  ECG channel covariance matrix,  $\hat{C}_x$ , is used in the construction of an approximate KLT matrix. Rows of the approximate KLT matrix are the eigenvectors of  $\hat{C}_x$ . Typical approximate KLT matrices can be found in [22].

Although there is no fast algorithm to compute the KL transform, the computational burden is not high because  $N = 8$ . The DCT can also be used as a linear transformer because it approximates the KLT.

FIGURE 3.4 A typical set of standard ECG lead waveforms  $x_i$ ,  $i = 0, 1, \dots, 7$ .

### 3.5.3 Compression of the Transform Domain Signals

In this section the compression of the uncorrelated transform domain signals  $y_k$ ,  $k = 0, 1, \dots, 7$ , are described. In Figure 3.5 a typical set of uncorrelated signals,  $y_k$ ,  $k = 0, 1, \dots, 7$ , are shown. The signals in Figure 3.5 are obtained by KL transforming the ECG signals,  $x_k$ ,  $k = 0, 1, \dots, 7$ , shown in Figure 3.4.

Transform domain signals,  $y_k$ ,  $k = 0, 1, \dots, 7$ , are divided into two classes according to their energy contents. The first class of signals,  $y_0, y_1, \dots, y_4$ , have higher energy than the second class of signals,  $y_5, y_6$ , and  $y_7$ . More bits are allocated to the high energy signals,  $y_0, y_1, \dots, y_4$ , compared to the low energy signals,  $y_5, y_6$ , and  $y_7$  in coding.

### 3.5.4 Subband Coder (SBC)

Higher energy signals,  $y_0(n), y_1(n), \dots, y_4(n)$ , contain more information than the low energy signals,  $y_5(n), y_6(n)$ , and  $y_7(n)$ . Therefore, the high energy signals,  $y_0(n), \dots, y_4(n)$  should be compressed very accurately. The signals,  $y_0(n), \dots, y_4(n)$ , are compressed using the SBC [17] because this coding scheme does not introduce any visual degradation as pointed out in the previous section [9].

FIGURE 3.5 Uncorrelated signals  $y_i$ ,  $i = 0, 1, 2, \dots, 7$ , corresponding to the ECG signals shown in Figure 3.4.

Each signal  $y_i$  is decomposed into four subsignals by using a filter bank in a tree-structured manner. In this way the signal  $y_i$  is divided into four consecutive bands,  $[l\pi/4, (l + 1)\pi/4]$ ,  $l = 0, 1, 2, 3$ , in the frequency domain [2]. For example,  $y_{i00}$  (the subsignal at branch A of Figure 3.2) comes from the lowpass frequency band,  $[0, \pi/4]$ , of the signal  $y_i$ . In the coding of the subband signals,  $y_{ijk}$ ,  $j = 0, 1$ ;  $k = 0, 1$ , the advantage is taken of the nonuniform distribution of energy in the frequency domain to judiciously allocate the bits. The number of bits used to encode each frequency band can be different, so the encoding accuracy is always maintained at the required frequency bands [2].

It is observed that the energy of the signal  $y_i$  is mainly concentrated in the lowest frequency band  $[0, \pi/4]$ . Because of this, the lowband subsignal  $y_{i,0,0}$  has to be carefully coded. High correlation among neighboring samples of  $y_{i,0,0}$  makes this signal a good candidate for efficient predictive or transform coding. The subsignals  $y_{i,0,0}$  are compressed using a DCT based scheme. After the application of DCT with a block size of 64 samples to the lowband subsignal,  $y_{i,0,0}$ , the transform domain coefficients,  $g_{i,0,0}(k)$ ,  $k = 0, 1, \dots, 63$  are obtained and they are thresholded and quantized. The coefficients whose magnitudes are above a preselected threshold,  $b$ , are retained and the other coefficients are discarded. Thresholded DCT coefficients are quantized for bit level representation. Thresholded and quantized nonzero coefficients are variable-length coded by using an amplitude table and the zero values are runlength coded. The amplitude and runlength lookup tables are Huffman coding tables which are obtained according to the histograms of the DCT coefficients [22].

In practice, ECG recording levels do not change from one recording to another. If drastic variations occur, first scale the input by an appropriate factor, then apply DCT.

Bandpass and highpass subsignals,  $y_{i,0,1}$ ,  $y_{i,1,0}$ ,  $y_{i,1,1}$  (branches B, C, and D), are coded using non-uniform quantizers. After quantization, a code assignment procedure is realized using variable length amplitude and runlength lookup tables for zero values. The look up tables are obtained according to the histograms of quantized subband signals.

The bit streams which are obtained from coding of four subband signals are multiplexed and stored. Appropriate decoders are assigned to each branch to convert the bit streams into time domain samples and the four-branch synthesis filter bank performs the reconstruction [17].

The low energy signals,  $y_5(n)$ ,  $y_6(n)$ ,  $y_7(n)$ , are also coded by using the SB coder previously explained. However, it is observed that all the subsignals except the subsignal at branch A of Figure 3.2 contain very little information when subband decomposition is applied to the signals  $y_5(n)$ ,  $y_6(n)$ ,  $y_7(n)$ . Due to this

**FIGURE 3.6** The original and reconstructed ECG lead signals I, II, V1, and V2 ( $CR = 6.17$ ,  $APRD = 6$ ).

fact, only the subsignals at branch A (lowband signals) are processed. The other branches which have very little energy are discarded.

Original and reconstructed ECG waveforms are shown in Figure 3.6 for  $CR = 6.17$  ( $CR = 7.98$ ) with  $PRD = 6.19\%$  when DCT (KLT) is used as the Linear Transformer. Recorded ECG signals are sampled at 500 Hz with 12 bit/sample resolution. Also, the raw ECG signals are filtered to attenuate the high frequency noise with a 33-tap equiripple Parks–McClellan FIR filter whose cutoff frequency is equal to 125 Hz. In this case a  $CR = 9.41$  is obtained for a  $PRD = 5.94\%$ .

The effect of compressing the data on diagnostic computer analysis results is tested on Cardionics program, which is derived from the Mount Sinai program developed by Pordy et al., in conjunction with CRO-MED Bionics Company [25]. Morphological measurements include (1) intervals — PR, QRS, QT, (2) “width”s — Q, R, S, R', S', T, P, (3) amplitudes — P, Q, R, R', S, S', T, J, and (4) areas of QRS and QRST. There was no difference in the measurement results of both the compressed and the original data.

It is experimentally observed that the multichannel technique produces better compression results than single channel schemes. Also, the computational complexity of the multichannel scheme is comparable to single channel ECG coding schemes and the algorithm can be implemented by using digital signal processor for real-time applications, such as transmission of ECG signals over telephone lines.

## 3.6 Conclusion

---

In this section biomedical signal compression methods are reviewed. Most of the biomedical data compression methods have been developed for ECG signals. However, these methods can be applied to other biomedical signals with some modifications.

It is difficult to compare the efficiency of biomedical data compression schemes because coding results of various data compression schemes are obtained under different recording conditions such as (1) sampling frequency, (2) bandwidth, (3) sample precision, and (4) noise level, which may drastically affect the currently used performance measures.

The Fourier transform of a signal  $x(t)$

$$X(f) = \int x(t)e^{-j2\pi ft} dt \quad (4.1)$$

is a useful tool for analyzing the spectral content of a stationary signal and for transforming difficult operations such as convolution, differentiation, and integration into very simple algebraic operations in the Fourier dual domain. The inverse Fourier transform equation

$$x(t) = \int X(f)e^{j2\pi ft} df \quad (4.2)$$

is a linear combination of complex sinusoids of infinite duration which implicitly assumes that each sinusoidal component is present at all times and, hence, that the spectral content of the signal does not

change with time. However, many signals in bioengineering are produced by biologic systems whose spectral characteristics can change rapidly with time. To analyze these rapid spectral changes one needs a two-dimensional, mixed time-frequency signal representation (TFR) that is analogous to a musical score with time represented along one axis and frequency along the other, indicating which frequency components (notes) are present at each time instant.

The first purpose of this chapter is to review several TFRs defined in Table 4.1 and to describe many of the desirable properties listed in Table 4.2 that an ideal TFR should satisfy. TFRs will be grouped into classes satisfying similar properties to provide a more intuitive understanding of their similarities, advantages, and disadvantages. Further, each TFR within a given class is completely characterized by a unique set of kernels that provide valuable insight into whether or not a given TFR (1) satisfies other ideal TFR properties, (2) is easy to compute, and (3) reduces nonlinear cross-terms. The second goal of this chapter is to discuss applications of TFRs to signal analysis and detection problems in bioengineering. Unfortunately, none of the current TFRs is ideal; some give erroneous information when the signal's spectra are rapidly time-varying. Researchers often analyze several TFRs side by side, keeping in mind the relative strengths and weaknesses of each TFR before drawing any conclusions.

## 4.1 One-Dimensional Signal Representations

---

The instantaneous frequency and the group delay of a signal are one-dimensional representations that attempt to represent temporal and spectral signal characteristics simultaneously. The instantaneous frequency of the signal

$$f_x(t) = \frac{1}{2\pi} \frac{d}{dt} \arg\{x(t)\} \quad (4.3)$$

has been used in communication theory to characterize the time-varying frequency content of narrow-band, frequency-modulated signals. It is a generalization of the fact that the frequency  $f_0$  of a complex sinusoidal signal  $x(t) = \exp(j2\pi f_0 t)$  is proportional to the derivative of the signal's phase. A dual concept used in filter analysis is the group delay

$$\tau_H(f) = -\frac{1}{2\pi} \frac{d}{df} \arg\{H(f)\} \quad (4.4)$$

which can be interpreted as the time delay or distortion introduced by the filter's frequency response  $H(f)$  at each frequency. Group delay is a generalization of the fact that time translations are coded in the derivative of the phase of the Fourier transform. Unfortunately, if the signal contains several signal components that overlap in time or frequency, then  $f_x(t)$  or  $\tau_H(f)$  only provides average spectral characteristics, which are not very useful.

## 4.2 Desirable Properties of Time-Frequency Representations

---

Mixed time-frequency representations (TFRs) map a one-dimensional signal into a two-dimensional function of time and frequency in order to analyze the time-varying spectral content of the signal. Before discussing any particular TFR in Table 4.1, it is helpful to first investigate what types of properties an "ideal" time-frequency representation should satisfy. The list of desirable TFR properties in Table 4.2 can be broken up conceptually into the following categories: covariance, statistical, signal analysis, localization, and inner products [Boashash, 1991; Claasen and Mecklenbräuker, 1980; Cohen, 1989; Flandrin, 1993; Hlawatsch and Boudreaux-Bartels, 1992]. The covariance properties  $P_1$  to  $P_6$  basically state that certain operations on the signal, such as translations, dilations, or convolution, should be preserved, that is, produce exactly the same operation on the signal's TFR. The second category of properties originates from the

desire to generalize the concepts of the one-dimensional instantaneous signal energy  $|x(t)|^2$  and power spectral density  $|x(f)|^2$  into a two-dimensional statistical energy distribution  $T_x(t_0, f_0)$  that provides a measure of the local signal energy or the probability that a signal contains a sinusoidal component of frequency  $f_0$  at time  $t_0$ . Properties  $P_7$  to  $P_{13}$  state that such an energy-distribution TFR should be real and nonnegative, have its marginal distributions equal to the signal's temporal and spectral energy densities  $|x(t)|^2$  and  $|X(f)|^2$ , respectively, and preserve the signal energy, mean, variance, and other higher-order moments of the instantaneous signal energy and power spectral density. The next category of properties,  $P_{14}$  to  $P_{18}$ , arises from signal-processing considerations. A TFR should have the same duration and bandwidth as the signal under analysis. At any given time  $t$ , the average frequency should equal the instantaneous frequency of the signal, while the average or center of gravity in the time direction should equal the group delay of the signal. These two properties have been used to analyze the distortion of audio systems and the complex FM sonar signals used by bats and whales for echolocation. Property  $P_{18}$  is the TFR equivalent of the duality property of Fourier transforms. The group of properties  $P_{19}$  to  $P_{24}$  constitutes ideal TFR localization properties that are desirable for high resolution capabilities. Here,  $d(a)$  is the Dirac function. These properties state that if a signal is perfectly concentrated in time or frequency, that is, an impulse or a sinusoid, then its TFR also should be perfectly concentrated at the same time or frequency. Properties  $P_{21}$  and  $P_{22}$  state that the TFRs of linear or hyperbolic spectral FM chirp signals should be perfectly concentrated along the chirp signal's group delay. Property  $P_{24}$  states that a signal modulated by a linear FM chirp should have a TFR whose instantaneous frequency has been sheared by an amount equal to the linear instantaneous frequency of the chirp. The last property, known as Moyal's formula or the unitarity property, states that TFRs should preserve the signal projections, inner products, and orthonormal signal basis functions that are used frequently in signal detection, synthesis, and approximation theory. Table 4.3 indicates which properties are satisfied by the TFRs listed in Table 4.1.

A TFR should be relatively easy to compute and interpret. Interpretation is greatly simplified if the TFR is linear, that is,

$$T_y(t, f) = \sum_{n=1}^N T_{x_n}(t, f) \quad \text{for } y(t) = \sum_{n=1}^N x_n(t) \quad (4.5)$$

However, energy is a quadratic function of the signal, and hence so too are many of the TFRs in Table 4.1. The nonlinear nature of TFRs gives rise to troublesome cross-terms. If  $y(t)$  contains  $N$  signal components or auto-terms  $x_n(t)$  in Equation 4.5, then a quadratic TFR of  $y(t)$  can have as many nonzero cross-terms as there are unique pairs of autoterms, that is,  $N(N - 1)/2$ . For many TFRs, these cross-terms are oscillatory and overlap with autoterms, obscuring visual analysis of TFRs.

Two common methods used to reduce the number of cross-terms are to reduce any redundancy in the signal representation and to use local smoothing or averaging to reduce oscillating cross-terms. TFR analysis of real, bandpass signals should be carried out using the analytic signal representation, that is, the signal added to times its Hilbert transform, in order to remove cross-terms between the positive- and negative-frequency axis components of the signal's Fourier transform. As we will see in upcoming sections, cross-term reduction by smoothing is often achieved at the expense of significant autoterm distortion and loss of desirable TFR properties.

### 4.3 TFR Classes

This section will briefly review Cohen's class of shift covariant TFRs, the Affine class of affine covariant TFRs, the Hyperbolic class (developed for signals with hyperbolic group delay), and the Power class (which is useful for signals with polynomial group delay). Each class is formed by grouping TFRs that satisfy two properties. They provide very helpful insight as to which types of TFRs will work best in different situations. Within a class, each TFR is completely characterized by a unique set of TFR-dependent kernels which can

**TABLE 4.1** List of Time–Frequency Representations (TFR) of a Signal  $x(t)$  Whose Fourier Transform Is  $X(f)$

Ackroyd distribution:	$ACK_x(t, f) = \text{Re} \left\{ x^*(t)X(f)e^{j2\pi ft} \right\}$
Affine Wigner distribution	$AWD_x(t, f; G, F) = \int G = \left(\frac{\nu}{f}\right) X\left(f\left(\frac{\nu}{f}\right) + \frac{\nu}{2}\right) X^*\left(f\left(\frac{\nu}{f}\right) - \frac{\nu}{2}\right) e^{j2\pi t\nu} d\nu$
Altes–Marinovic distribution:	$AM_x(t, f) =  f  \int X(fe^{u/2})X^*(fe^{-u/2})e^{j2\pi ftu} du =  f  \iint WAF_x(\tau, e^\beta) e^{j2\pi(\tau f\beta - f\tau)} d\tau d\beta$
(Narrowband) ambiguity function:	$AF_x(\tau, \nu) = \int x\left(t + \frac{\tau}{2}\right) x^*\left(t - \frac{\tau}{2}\right) e^{-j2\pi\nu t} dt = \int X\left(f + \frac{\nu}{2}\right) X^*\left(f - \frac{\nu}{2}\right) e^{j2\pi f\tau} df$
Andrieux et al. distribution:	$AND_x(t, f) = \iint \frac{1}{\sigma_{(t-t')}\sigma_{(f-f')}} \exp\left[-\left(\frac{(t-t')^2}{2\sigma_t^2} + \frac{(f-b_{(t-t')}(t-t'))^2}{2\sigma_f^2}\right)\right] WDX(t', f') dt' df'$
	where for $x(t) = e^{j2\pi\psi(t)}$ , then $b_t = \frac{d^2}{dt^2}\psi(t)$ , $\sigma_t = \left \frac{d^3}{dt^3}\psi(t)\right ^{-1/3}$ , and $2\pi\sigma_t\sigma_f = \frac{1}{2}$
Autocorrelation function:	
Temporal:	$act_x(\tau) = \int x^*(t)x(t+\tau) dt = \int  X(f) ^2 e^{j2\pi f\tau} df$
Spectral:	$ACF_X(\nu) = \int X^*(f)X(f+\nu) df = \int  x(t) ^2 e^{-j2\pi t\nu} dt$
Bertram $P_k$ distribution:	$BkD_x(t, f; \mu_k) =  f  \int X(\lambda_k(u))X^*(f\lambda_k(-u))\mu_k(u)e^{j2\pi f(\lambda_k(u)-\lambda_k(-u))} du$
with $\lambda_0(u) = \frac{u/2e^{u/2}}{\sinh(u/2)}$ , $\lambda_1(u) = \exp\left[\frac{1+ue^{-u}}{e^{-u}-1}\right]$ , $\lambda_k(u) = \left[\frac{e^u-1}{e^{-ku}-1}\right]^{1/(k-1)}$ $k \neq 0, 1, \mu_k(u) = \mu_k(-u) > 0$	
Born–Jordan distribution:	$BJD_x(t, f) = \int \frac{1}{ \tau } \left[ \int_{t- \tau /2}^{t+ \tau /2} x\left(t' + \frac{\tau}{2}\right) x^*\left(t' - \frac{\tau}{2}\right) dt' \right] e^{-j2\pi f\tau} d\tau$
Butterworth distribution:	$BUD_x(t, f) = \iint \left(1 + \frac{\tau}{\tau_0}\right)^{2M} \left(\frac{\nu}{\nu_0}\right)^{2N} AF_x(\tau, \nu) e^{j2\pi(\nu t - f\tau)} d\tau d\nu$
Choi–Williams exponential distribution:	$CWD_x(t, f) = \iint \sqrt{\frac{\sigma}{4\pi \tau }} \exp\left[-\frac{\sigma}{4}\left(\frac{t-t'}{\tau}\right)^2\right] x\left(t' + \frac{\tau}{2}\right) x^*\left(t' - \frac{\tau}{2}\right) e^{-j2\pi f\tau} dt' d\tau$

Cohen's nonnegative distribution:	$CND_X(t, f) = \frac{ x(t) ^2  X(f) ^2}{E_x} [1 + c\rho(\xi_x(t), \eta_x(f))]$
	$\text{with } \xi_x(t) = \frac{1}{E_x} \int_{-\infty}^t  x(\tau) ^2 d\tau, \eta_x(f) = \frac{1}{E_x} \int_{-\infty}^f  X(f') ^2 df', E_x = \int  x(t) ^2 dt$
Cone-Kernel distribution:	$CKD_X(t, f) = \int g(\tau) \left[ \int_{t- \tau /2}^{t+ \tau /2} x\left(t' + \frac{\tau}{2}\right) x^*\left(t' - \frac{\tau}{2}\right) dt' \right] e^{-j2\pi f\tau} d\tau$
Cumulative attack spectrum:	$CAS_X(t, f) = \left  \int_{-\infty}^t x(\tau) e^{-j2\pi f\tau} d\tau \right ^2$
Cumulative decay spectrum:	$CDS_X(t, f) = \left  \int_t^{\infty} x(\tau) e^{-j2\pi f\tau} d\tau \right ^2$
Flandrin $D$ -distribution:	$FC_X(t, f) =  f  \int X\left(f\left[1 + \frac{u}{4}\right]\right) X^*\left(f\left[1 - \frac{u}{4}\right]\right) \left[1 - \left(\frac{u}{4}\right)^2\right] e^{j2\pi fu} du$
Gabor expansion, $G_{G_X}(n, k, g)$ :	$x(t) = \sum_n \sum_k G E_X(nk; g) \xi(t - n\Delta T) e^{j2\pi(k\Delta F)t}$
Generalized Altes distribution:	$GAM_X(t, f; \alpha) =  f  \int e^{-\alpha u} X\left(fe^{(1/2) - \alpha} u\right) X^*\left(fe^{-(1/2) + \alpha} u\right) e^{j2\pi f u} du$
Generalized exponential distribution:	$GED_X(t, f) = \iint \exp\left[-\left(\frac{\tau}{\tau_0}\right)^{2M} \left(\frac{\nu}{\nu_0}\right)^{2N}\right] A F_X(\tau, \nu) e^{j2\pi(\nu\nu - f\tau)} d\tau d\nu$
Generalized Wigner distribution:	$GWD_X(t, f; \hat{\alpha}) = \int x\left(t + \left(\frac{1}{2} + \hat{\alpha}\right)\tau\right) x^*\left(t - \left(\frac{1}{2} - \hat{\alpha}\right)\tau\right) e^{-j2\pi f\tau} d\tau$
Hyperbolic ambiguity function:	$HAF_X(\zeta, \beta) = \int_0^{\infty} X(fe^{\beta/2}) X^*(fe^{-\beta/2}) e^{j2\pi\zeta \ln(f/f_0)} df$
Hyperbolic wavelet transform:	$HWT_X(t, f; \Gamma) = \sqrt{\frac{f_r}{f}} \int_0^{\infty} X(\xi) \Gamma^*\left(\frac{f_r}{f}\xi\right) e^{j2\pi f t \ln(\xi/f_r)} d\xi$
Hyperbologram:	$HYP_X(t, f; \Gamma) = \left  \sqrt{\frac{f_r}{f}} \int_0^{\infty} X(\xi) \Gamma^*\left(\frac{f_r}{f}\xi\right) e^{j2\pi f t \ln(\xi/f_r)} d\xi \right ^2 =  HWT_X(t, f; \Gamma) ^2$
Levin distribution:	$LD_X(t, f) = -\frac{d}{dt} \int_t^{\infty} x(\tau) e^{-j2\pi f\tau} d\tau \Big _t^2$
Margineau-Hill distribution:	$MH_X(t, f) = \text{Re} \left\{ x(t) X^*(f) e^{-j2\pi f t} \right\}$
Multiform, Tiltable distributions:	Let $\tilde{\mu}(\tilde{\tau}, \tilde{\nu}; \alpha, r, \beta, \gamma) = \left((\tilde{\tau})^2 (\tilde{\nu})^2\right)^\alpha + \left((\tilde{\tau})^2\right)^\alpha (\tilde{\nu})^2 + 2r \left((\tilde{\tau}\tilde{\nu})^\beta\right)^\gamma$
Butterworth:	$MTBD_X(t, f) = \iint \left[ 1 - \tilde{\mu}^{2\lambda} \left( \frac{\tau}{\tau_0}, \frac{\nu}{\nu_0}; \alpha, r, \beta, \gamma \right) \right]^{-1} A F_X(\tau, \nu) e^{j2\pi(\nu\nu - f\tau)} d\tau d\nu$

(Continued)

**TABLE 4.1** (Continued) List of Time-Frequency Representations (TFR) of a Signal  $x(t)$  Whose Fourier Transform Is  $X(f)$

Exponential:	$MTED_X(t, f) = \iint \exp \left\{ -\pi \mu^{2\lambda} \left( \frac{\tau}{\tau_0}, \frac{\nu}{\nu_0}; \alpha, r, \beta, \gamma \right) \right\} AF_X(\tau, r) e^{j2\pi(\nu\nu - f\tau)} d\tau d\nu$
(Inverse) Chebyshev:	$MT(I)C_X(t, f) = \iint \left[ 1 + \epsilon^2 C_\lambda^{\pm 2} \left( \mu \left( \frac{\tau}{\tau_0}, \frac{\nu}{\nu_0}; \alpha, r, \beta, \gamma \right)^{\pm 1} \right) \right]^{-1} AF_X(\tau, \nu) e^{j2\pi(\nu\nu - f\tau)} d\tau d\nu$ where $C_\lambda(a)$ is a Chebyshev polynomial of order $\lambda$
Nuttall-Griffin distribution:	$ND_X(t, f) = \iint \exp \left\{ -\pi \left[ \left( \frac{\tau}{\tau_0} \right)^2 + \left( \frac{\nu}{\nu_0} \right)^2 + 2r \left( \frac{\tau\nu}{\tau_0\nu_0} \right) \right] \right\} AF_X(\tau, \nu) e^{j2\pi(\nu\nu - f\tau)} d\tau d\nu$
Page distribution: kth power	$PD_X(t, f) = \frac{d}{dt} \left  \int_{-\infty}^t x(\tau) e^{-j2\pi f\tau} d\tau \right ^2$
Ambiguity function:	$B_X^{(\kappa)}(\zeta, \beta) = AF_{W_{\kappa X}} \left( \frac{\zeta}{f}, f, \beta \right), (W_{\kappa X})(f) = \frac{1}{\sqrt{ f  \tau_\kappa (f \xi_\kappa^{-1}(f/f_r))}} X \left( f \xi_\kappa^{-1} \left( \frac{f}{f_r} \right) \right)$
Central member:	$AM_X^{(\kappa)}(t, f) = WD_{W_{\kappa X}} \left( \frac{t}{f}, f, \beta \right), \tau_\kappa(f) = \frac{d}{df} \xi_\kappa \left( \frac{f}{f_r} \right)$ where $\xi_\kappa(b) = \begin{cases} \text{sgn}(b) b ^\kappa, & b \in \mathcal{R}, \text{ for } \kappa \neq 0 \\ \ln(b), & b > 0 \text{ for } \kappa = 0 \end{cases}$ and $\xi_\kappa^{-1}(b) = \begin{cases} \text{sgn}(b) b ^{1/\kappa}, & b \in \mathcal{R}, \kappa \neq 0 \\ e^b, & b > 0, \kappa = 0 \end{cases}$
Power spectral density:	$PSD_X(f) =  X(f) ^2 = \int \text{act}_X(\tau) e^{-j2\pi f\tau} d\tau$
Pseudo-Altes distribution:	$PAD_X(t, f; \Gamma) = f_r \int_0^\infty AM_\Gamma \left( 0, f_r, \frac{f}{f_r} \right) AM_X \left( \frac{t}{f_r}, f' \right) \frac{df'}{f_r}$
Pseudo-Wigner distribution:	$PWD_X(t, f; \eta) = \int x \left( t + \frac{\tau}{2} \right) x^* \left( t - \frac{\tau}{2} \right) \eta \left( \frac{\tau}{2} \right) e^{-j2\pi f\tau} d\tau$
Radially adaptive Gaussian distribution:	$RAGD_X(t, f) = \iint \exp \left[ -\frac{(\tau/\tau_0)^2 + (\nu/\nu_0)^2}{2\sigma_X^2(\theta)} \right] AF_X(\tau, \nu) e^{j2\pi(\nu\nu - f\tau)} d\tau d\nu$ where $\theta = \arctan \left[ \frac{\nu/\nu_0}{\tau/\tau_0} \right]$

Real generalized Wigner distribution:	$RGWD_x(t, f; \tilde{\alpha}) = \text{Re} \left\{ \int x \left( t + \left( \frac{1}{2} - \tilde{\alpha} \right) \tau \right) x \left( t - \left( \frac{1}{2} - \tilde{\alpha} \right) \tau \right) e^{-j2\pi f \tau} d\tau \right\}$
Reduced interference distribution:	$RID_x(t, f; S_{RID}) = \iint \frac{1}{ \tau } S_{RID} \left( \frac{t-t'}{\tau} \right) x \left( t + \frac{\tau}{2} \right) x^* \left( t' + \frac{\tau}{2} \right) e^{-j2\pi f \tau} dt' d\tau$
with $S_{RID}(\beta) \Big _{\beta=0} = 1$ , $\left\{ \frac{d}{d\beta} S_{RID}(\beta) \Big _{\beta=0} = 0 \right\}$ , $\left\{ S_{RID}(\alpha) = 0 \text{ for }  \alpha  > \frac{1}{2} \right\}$	
Rihaczek distribution:	$RD_x(t, f) = x(t)X^*(f)e^{-j2\pi f t}$
Running spectrum, past and future:	$RSE_x(t, f) = \int_{-\infty}^t x(u)e^{-j2\pi f u} du, RSE_x(t, f) = \int_t^{\infty} x(u)e^{-j2\pi f u} du$
Scalogram:	$SCAL_x(t, f; \gamma) = \left  \int x(\tau) \sqrt{\left  \frac{f}{f'} \right } \gamma^* \left( \frac{f}{f'} (\tau - t) \right) d\tau \right ^2 =  WT_x(t, f; \gamma) ^2$
Short-time Fourier transform:	$STFT_x(t, f; \gamma) = \int x(\tau) \gamma^*(\tau - t) e^{-j2\pi f \tau} d\tau = e^{-j2\pi f t} \int X(f') \Gamma^*(f' - f) e^{j2\pi f' t'} df'$
Smoothed Pseudo-Altes distribution:	$SPAD_X(t, f; \Gamma, g) = \int g(tf - c) PAD_x \left( \frac{c}{f}, f; \Gamma \right) dc$
Smoothed Pseudo-Wigner distribution:	$SPWD_x(t, f; \gamma, \eta) = \iint \gamma(t-t') \eta^* \left( \frac{\tau}{2} \right) \eta \left( -\frac{\tau}{2} \right) x \left( t' + \frac{\tau}{2} \right) x^* \left( t' - \frac{\tau}{2} \right) e^{-j2\pi f \tau} dt' d\tau$
Spectrogram:	$SPEC_x(t, f; \gamma) = \left  \int x(\tau) \gamma^*(\tau - t) e^{-j2\pi f \tau} d\tau \right ^2 =  STFT_x(t, f; \gamma) ^2$
Unterberger active distribution:	$UAD_x(t, f) = f \int_0^{\infty} X(fu) X^*(f/u) [1 + u^{-2}] e^{j2\pi f t} (u-1/u) du$
Unterberger passive distribution:	$UPD_x(t, f) = 2f \int_0^{\infty} X(fu) X^*(f/u) [u^{-1}] e^{j2\pi f t} (u-1/u) du$
Wavelet transform:	$WT_x(t, f; \gamma) = \int x(\tau) \sqrt{\left  \frac{f}{f'} \right } \gamma^* \left( \frac{f}{f'} (\tau - t) \right) d\tau = \int X(f') \sqrt{\left  \frac{f}{f'} \right } \Gamma^* \left( \frac{f'}{f} \right) e^{j2\pi f' t'} df'$
Wideband ambiguity function:	$WAF_x(\tau, \alpha) = \int_0^{\infty} X(f\sqrt{\alpha}) X^*(f\sqrt{\alpha}) e^{j2\pi f \tau} df$
Wigner distribution:	$WD_x(t, f) = \int x \left( t + \frac{\tau}{2} \right) x^* \left( t - \frac{\tau}{2} \right) e^{-j2\pi f \tau} d\tau = \int X \left( f + \frac{\nu}{2} \right) X^* \left( f - \frac{\nu}{2} \right) e^{j2\pi \nu t} d\nu$

**TABLE 4.2** List of Desirable Properties for Time-Frequency Representations and Their Corresponding Kernel Constraints

Property Name	TFR Property	Kernel Constraints for Cohen's Class	Kernel Constraints for Hyperbolic Class
$P_1$ : Frequency-shift cov- ariant	$T_y(t, f) = T_x(t, f - f_0)$ for $y(t) = x(t)e^{j2\pi f_0 t}$	Always satisfied	
$P_2$ : Time-shift covariant	$T_y(t, f) = T_x(t - t_0, f)$ for $y(t) = x(t - t_0)$	Always satisfied	$\Psi_H(\zeta, \beta) = B_H(\beta)e^{-j2\pi\zeta \ln G(\beta)}$ with $G(\beta) = \frac{\beta/2}{\sinh(\beta/2)}$
$P_3$ : Scale covariant	$T_y(t, f) = T_x(at, f/a)$ for $y(t) = \sqrt{ a }x(at)$	$\Psi_C(\tau, \nu) = S_C(\tau\nu)$	Always satisfied
$P_4$ : Hyperbolic time shift	$T_y(t, f) = T_x(t - c/f, f)$ if $Y(f) = \exp\left(-j2\pi c \ln \frac{f}{f_r}\right) X(f)$		Always satisfied
$P_5$ : Convolution covariant	$T_y(t, f) = \int T_h(t - \tau, f) T_x(\tau, f) d\tau$ for $y(t) = \int h(t - \tau)x(\tau) d\tau$	$\Psi_C(\tau, \nu) = e^{\tau P_C(\nu)}$	$\Phi_H(b_1, \beta)\Phi_H(b_2, \beta) = e^{b_1}$ $\Phi_H(b_1, \beta)\delta(b_1 - b_2)$
$P_6$ : Modulation covariant	$T_y(t, f) = \int T_h(t, f - f') T_x(t, f') df'$ for $y(t) = h(t)x(t)$	$\Psi_C(\tau, \nu) = e^{\nu P_C(\tau)}$	
$P_7$ : Real-valued	$T_x^*(t, f) = T_x(t, f)$	$\Psi_C^*(-\tau, -\nu) = \Psi_C(\tau, \nu)$	$\Psi_H^*(-\zeta, -\beta) = \Psi_H(\zeta, \beta)$
$P_8$ : Positivity	$T_x(t, f) \geq 0$	$\Psi_C(\tau, \nu) = AP_\gamma(-\tau, -\nu)$	$\Psi_H(\zeta, \beta) = HA\Gamma_\gamma(-\zeta, -\beta)$
$P_9$ : Time marginal	$\int T_x(t, f) df =  x(t) ^2$	$\Psi_C(0, \nu) = 1$	
$P_{10}$ : Frequency marginal	$\int T_x(t, f) dt =  X(f) ^2$	$\Psi_C(\tau, 0) = 1$	$\Psi_H(\zeta, 0) = 1$
$P_{11}$ : Energy distribution	$\iint T_x(t, f) dt df = \int  X(f) ^2 df$	$\Psi_C(0, 0) = 1$	$\Psi_H(0, 0) = 1$
$P_{12}$ : Time moments	$\iint t^n T_x(t, f) dt df = \int t^n  x(t) ^2 dt$	$\Psi_C(0, \nu) = 1$	
$P_{13}$ : Frequency moments	$\iint f^n T_x(t, f) dt df = \int f^n  X(f) ^2 df$	$\Psi_C(\tau, 0) = 1$	
$P_{14}$ : Finite time support	$T_x(t, f) = 0$ for $t \notin (t_1, t_2)$ if $x(t) = 0$ for $t \notin (t_1, t_2)$	$\varphi_C(t, \tau) = 0, \left  \frac{t}{\tau} \right  > \frac{1}{2}$

A ✓ indicates that the TFR can be shown to satisfy the given property. A number following the ✓ indicates that additional constraints are needed to satisfy the property. The constraints are as follows: (1):  $M = N$ ; (2):  $M > 1/2$ ; (3):  $N > 1/2$ ; (4):  $g(\tau)$  even; (5):  $|\alpha| < 1/2$ ; (6):  $M = 1/2$ ; (7):  $N = 1/2$ ; (8):  $\int_0^\infty |\Gamma(f)|^2 df = 1$ ; (9):  $\alpha = 1$ ; (10):  $r = 0, \alpha = 1, \gamma = 1/4$ ; (11):  $\alpha \neq 1$ ; (12):  $|\rho\Gamma(0)|^2 = (1/fr)$ ; (13):  $|\eta(0)| = 1$ ; (14):  $\eta(0) = 1$ ; (15):  $SRID(\beta)$  even; (16):  $\int |\Gamma(b)|^2 db/|b| = 1$ ; (17):  $g(c) \in \text{Real}$ ; (19):  $\Gamma(0)|\eta(0)|^2 = 1$ ; (20):  $\int |\gamma(t)|^2 dt = 1$ . In the second row, the letters  $c, a, h,$  and  $p$  indicate that the corresponding TFR is a member of the Cohen, Affine, Hyperbolic and  $\kappa$ th Power class, respectively.

be compared against a class-dependent list of kernel constraints in Table 4.2 and Table 4.6 to quickly determine which properties the TFR satisfies.

### 4.3.1 Cohen's Class of TFRs

Cohen's class consists of all quadratic TFRs that satisfy the frequency-shift and time-shift covariance properties, that is, those TFRs with a check in the first two property rows in Table 4.3 [Claasen and Mecklenbräuker, 1980; Cohen, 1989; Flandrin, 1993; Hlawatsch and Boudreaux-Bartels, 1992]. Time- and frequency-shift covariances are very useful properties in the analysis of speech, narrowband Doppler systems, and multipath environments. Any TFR in Cohen's class can be written in one of the four equivalent "normal forms":

$$C_x(t, f; \Psi_C) = \iint \varphi_C(t - t', \tau) x\left(t' + \frac{\tau}{2}\right) x^*\left(t' - \frac{\tau}{2}\right) e^{-j2\pi f\tau} dt' d\tau \quad (4.6)$$

$$= \iint \Phi_C(f - f', \nu) X\left(f' + \frac{\nu}{2}\right) X^*\left(f' - \frac{\nu}{2}\right) e^{j2\pi t\nu} df' d\nu \quad (4.7)$$

$$= \iint \psi_C(t - t', f - f') WD_x(t', f') dt' df' \quad (4.8)$$

$$= \iint \Psi_C(\tau, \nu) AF_x(\tau, \nu) e^{j2\pi(t\nu - f\tau)} d\tau d\nu \quad (4.9)$$

Each normal form is characterized by one of the four kernels  $\varphi_C(f, \tau)$ ,  $\phi_C(f, \nu)$ ,  $\psi_C(t, f)$ , and  $\Psi_C(\tau, \nu)$  which are interrelated by the following Fourier transforms:

$$\varphi_C(t, \tau) = \iint \Phi_C(f, \nu) e^{j2\pi(f\tau + \nu t)} df d\nu = \int \Psi_C(\tau, \nu) e^{j2\pi \nu t} d\nu \quad (4.10)$$

$$\psi_C(t, f) = \iint \Psi_C(\tau, \nu) e^{j2\pi(\nu t - f\tau)} d\tau d\nu = \int \Phi_C(f, \nu) e^{j2\pi \nu t} d\nu \quad (4.11)$$

The kernels for the TFRs in Cohen's class are given in Table 4.4.

The four normal forms offers various computational and analysis advantages. For example, the first two normal forms can be computed directly from the signal  $x(t)$  or its Fourier transform  $X(f)$  via a one-dimensional convolution with  $\varphi_C(t, \tau)$  or  $\Phi_C(f, \nu)$ . If  $\varphi_C(t, \tau)$  is of fairly short duration, then it may be possible to implement Equation 4.6 on a digital computer in real time using only a small number of signal samples. The third normal form indicates that any TFR in Cohen's shift covariant class can be computed by convolving the TFR-dependent kernel  $\psi_C(t, f)$  with the Wigner distribution (WD) of the signal, defined in Table 4.1. Hence the WD is one of the key members of Cohen's class, and many TFRs correspond to smoothed WDs, as can be seen in the top of Table 4.5. Equation 4.11 and the fourth normal form in Equation 4.9 indicate that the two-dimensional convolution in Equation 4.8 transforms to multiplication of the Fourier transform of the kernel  $\psi_C(t, f)$  with the Fourier transform of the WD, which is the ambiguity function (AF) in Table 4.1. This last normal form provides an intuitive interpretation that the "AF domain" kernel  $\Psi_C(\tau, \nu)$  can be thought of as the frequency response of a two-dimensional filter.

The kernels in Equation 4.6 to Equation 4.11 are signal-independent and provide valuable insight into the performance of each Cohen class TFR, regardless of the input signal. For good cross-term reduction and little autoterm distortion, each TFR kernel  $\Psi_C(\tau, \nu)$  given in Table 4.4 should be as close as possible to an ideal low-pass filter. If these kernels satisfy the constraints in the third column of Table 4.2, then the TFR properties in the first column are guaranteed to always hold [Claasen and Mecklenbräuker, 1980; Hlawatsch and Boudreaux-Bartels, 1992]. For example, the last row of Table 4.2 indicates that Moyal's

Pseudo-Wigner distribution	$PWD_x(t, f; \eta) = \int WD_\eta(0, f - f') WD_x(t, f') df'$
Scalogram	$SCAL_x(t, f; \gamma) = \iint WD_\gamma\left(\frac{f}{f_r}(t' - t), f_r \frac{f'}{f}\right) WD_x(t', f') dt' df'$
Smoothed Pseudo-Wigner distribution	$SPWD_x(t, f; \gamma, \eta) = \iint \gamma(t - t') WD_\eta(0, f - f') WD_x(t', f') dt' df'$
Spectrogram	$SPEC_x(t, f; \gamma) = \iint WD_\gamma(t' - t, f' - f) WD_x(t', f') dt' df'$
Altes distribution	$AM_X(t, f) = WD_{WX}\left(\frac{tf}{f}, f_r \ln \frac{f}{f_r}\right)$
$\kappa$ th Power Altes distribution	$AM_X^{(\kappa)}(t, f) = WD_{W_\kappa X}\left(\frac{t}{\kappa  f_r/f ^{(\kappa-1)/\kappa}}, f_r \text{sgn}(f)  f/f_r ^\kappa\right), \kappa \neq 0$
Hyperbologram	$HYP_X(t, f; \Gamma) = \int_{-\infty}^{\infty} \int_0^{\infty} WD_{W\Gamma}\left(t' - \frac{tf}{f_r}, f' - f_r \ln \frac{f}{f_r}\right) WD_{WX}(t', f') dt' df'$
Pseudo-Altes distribution	$PAD_X(t, f; \Gamma) = f_r \int_0^{\infty} WD_{W\Gamma}\left(0, f_r \ln \frac{f}{f'}\right) WD_{WX}\left(\frac{tf}{f_r}, f_r \ln \frac{f'}{f_r}\right) \frac{df'}{f'}$
Smoothed Pseudo-Altes distribution	$SPAD_X(t, f; \Gamma, g) = f_r \int_{-\infty}^{\infty} \int_0^{\infty} g(tf - c) WD_{W\Gamma}\left(0, f_r \ln \frac{f}{f'}\right) WD_{WX}\left(\frac{c}{f_r}, f_r \ln \frac{f'}{f_r}\right) \frac{df'}{f'} dc$

where  $f_r > 0$  is a positive reference frequency,  $(\mathcal{W}H)(f) = \sqrt{e^f/f_r} H(f, e^f/f_r)$ ,  $(\mathcal{W}_\kappa H)(f) = | \kappa | f_r / f |^{(\kappa-1)/\kappa} H(f_r \text{sgn}(f) |f/f_r|^\kappa)$ ,  $\kappa \neq 0$ , and  $\text{sgn}(f) = \begin{cases} 1, & f > 0 \\ -1, & f < 0 \end{cases}$  members of the affine class are the Bertrands'  $P_0$  distribution, the scalogram, and the Unterberger distributions. All are defined in Table 4.1, and their kernel forms and TFR property constraints are listed in Table 4.6. Because of the scale covariance property, many TFRs in the Affine class exhibit constant-Q behavior, permitting multiresolution analysis.

formula is satisfied by any TFR whose AF domain kernel, listed in the third column of Table 4.4, has unit modulus, for example, the Rihaczek distribution. Since the AF domain kernel of the WD is equal to one, that is,  $YWD(\tau, \nu) = 1$ , then the WD automatically satisfies the kernel constraints in Table 4.2 for properties  $P_9$  to  $P_{13}$  and  $P_{16}$  to  $P_{21}$  as well as Moyal's formula. However, it also acts as an all-pass filter, passing all cross-terms. The Choi-Williams Gaussian kernel in Table 4.4 was formulated to satisfy the marginal property constraints of having an AF domain kernel equal to one along the axes and to be a low-pass filter that reduces cross-terms.

### 4.3.2 Affine Class of TFRs

TFRs that are covariant to scale changes and time translations, that is, properties  $P_2$  and  $P_3$  in Tables 4.2 and 4.3, are members of the *Affine class* [Bertrand chapter in Boashash, 1991; Flandrin, 1993].

The scale covariance property  $P_3$  is useful when analyzing wideband Doppler systems, signals with fractal structure, octave-band systems such as the cochlea of the inner ear, and detecting short-duration "transients." Any Affine class TFR can be written in four "normal form" equations similar to those of Cohen's class:

$$A_x(t, f; \Psi_A) = |f| \iint \varphi_A(f(t' - t), f\tau) x(t + \tau/2) x^*(t - \tau/2) dt' d\tau \quad (4.12)$$

$$= \frac{1}{|f|} \iint \Phi_A\left(\frac{f'}{f}, \frac{\nu}{f}\right) X(f' + \nu/2) X^*(f' - \nu/2) e^{j2\pi t\nu} df' d\nu \quad (4.13)$$

$$= \iint \psi_A\left(f(t - t'), \frac{f'}{f}\right) WD_x(t', f') dt' df' \quad (4.14)$$

$$= \iint \Psi_A\left(f\tau, \frac{\nu}{f}\right) AF_x(\tau, \nu) e^{j2\pi t\nu} d\tau d\nu \quad (4.15)$$

TABLE 4.6 Affine Class Kernels and Constraints

FD	$\left[ 1 - \left( \frac{\beta}{4} \right)^2 \right] e^{j2\pi\zeta \left[ 1 + (\beta/4)^2 \right]}$	$\left[ 1 - \left( \frac{\beta}{4} \right)^2 \right] \delta \left( b - \left[ 1 + (\beta/4)^2 \right] \right)$
GWD	$e^{-j2\pi\zeta [1 - \xi\beta]}$	$\delta(b - [1 - \xi\beta])$
SCAL	$AF_{\gamma}(-\zeta/f_r, -f_r\beta)$	$f_r \Gamma(f_r(b - \beta/2)) \Gamma^*(f_r(b + \beta/2))$
UAD	$e^{-j2\pi\zeta \sqrt{1 + \beta^2/4}}$	$\delta \left( b = \sqrt{1 + \beta^2/4} \right)$
UPD	$\left[ 1 + \beta^2/4 \right]^{-1/2} e^{-j2\pi\zeta \left[ 1 + \beta^2/4 \right]}$	$\left[ 1 + \beta^2/4 \right]^{-1/2} \delta \left( b - \sqrt{1 + \beta^2/4} \right)$
WD	$e^{-j2\pi\zeta}$	$\delta(b - 1)$
Property	Constraint on Kernel	
$P_1$ : Frequency shift	$\psi_A(\alpha_0 a, (b - 1)/\alpha_0 + 1) = \psi_A(a, b)$	
$P_2$ : Time shift	Always satisfied	
$P_3$ : Scale covariance	Always satisfied	
$P_4$ : Hyperbolic time shift	$\Phi_A(b, \beta) = G_A(\beta) \delta \left( b = \frac{\beta}{2} \coth \frac{\beta}{2} \right)$	
$P_5$ : Convolution	$\psi_A(\zeta, \beta) = e^{\xi P_A(\beta)}$	
$P_7$ : Real-valued	$\psi_A(\zeta, \beta) = \psi_A^*(-\zeta, -\beta)$	
$P_9$ : Time marginal	$\int \Phi_A(b, -2b) \frac{db}{ b } = 1$	
$P_{10}$ : Frequency marginal	$\Phi_A(b, 0) = \delta(b - 1)$	
$P_{11}$ : Energy distribution	$\int \Phi_A(b, 0) \frac{db}{ b } = 1$	
$P_{14}$ : Finite time support	$\varphi_A(a, \zeta) = 0, \left  \frac{a}{\zeta} \right  > \frac{1}{2}$	
$P_{15}$ : Finite frequency support	$\Phi_A(b, \beta) = 0, \left  \frac{b-1}{\beta} \right  > \frac{1}{2}$	
$P_{17}$ : Group delay	$\Phi_A(b, 0) = \delta(b - 1)$ and $\frac{\partial}{\partial \beta} \Phi_A(b, \beta)  _{\beta=0} = 0$	
$P_{19}$ : Frequency localization	$\Phi_A(b, 0) = \delta(b - 1)$	
$P_{25}$ : Moyal's formula	$\int \Phi_A^*(b\beta, \tilde{\eta}\beta) \Phi_A(\beta, \tilde{\eta}\beta) d\beta = \delta(b - 1), \forall \tilde{\eta}$	

The Affine class kernels are interrelated by the same Fourier transforms given in Equation 4.10 and Equation 4.11. Note that the third normal form of the Affine class involves an Affine smoothing of the WD. Well-known members of the Affine class are the Bertrands'  $P_0$  distribution, the scalogram, and the Unterberger distributions. All are defined in Table 4.1, and their kernel forms and TFR property constraints are listed in Table 4.6. Because of the scale covariance property, many TFRs in the Affine class exhibit constant-Q behavior, permitting multiresolution analysis.

### 4.3.3 Hyperbolic Class of TFRs

The Hyperbolic class of TFRs consists of all TFRs that are covariant to scale changes and hyperbolic time shifts, that is, properties  $P_3$  and  $P_4$  in Table 4.2 [Papandreou et al., 1993]. They can be analyzed using the

**TABLE 4.7** Kernels of the Hyperbolic Class of Time–Frequency Representations

$$= \iint \Phi_H \left( \ln \frac{f}{f_r} - b, \beta \right) f_r e^b X(f_r e^{b+\beta/2}) X^*(f_r e^{b-\beta/2}) e^{j2\pi t f \beta} db d\beta \tag{4.17}$$

$$= \int_{-\infty}^\infty \int_0^\infty \psi_H \left( tf - t'f', \ln \frac{f}{f'} \right) AM_X(t', f') dt' df' \tag{4.18}$$

$$= \iint \Psi_H(\zeta, \beta) HAF_X(\zeta, \beta) e^{j2\pi(tf\beta - \lceil \ln(f/f_r)\zeta \rceil)} d\zeta d\beta \tag{4.19}$$

where  $AM_X(t, f)$  is the Altes distribution and  $HAF_X(\zeta, \beta)$  is the hyperbolic ambiguity function defined in Table 4.1,  $v_X(c, \zeta)$  is defined in Table 4.7,  $(\mathcal{W}X)(f) = \sqrt{e^f/f_r} X(f_r e^f/f_r)$  is a unitary warping on the frequency axis of the signal, and the kernels are interrelated via the Fourier transforms in Equation 4.10 and Equation 4.11.

Table 4.3 reveals that the Altes-Marinovic, the Bertrands’  $P_0$ , and the hyperbologram distributions are members of the Hyperbolic class. Their kernels are given in Table 4.7, and kernel property constraints are given in Table 4.2. The hyperbolic TFRs give highly concentrated TFR representations for signals with hyperbolic group delay. Each Hyperbolic class TFR, kernel, and property corresponds to a warped version of a Cohen’s class TFR, kernel, and property, respectively. For example, Table 4.5 shows that the Altes distribution is equal to the WD after both the signal and the time–frequency axes are warped appropriately. The WD’s perfect location of linear FM chirps ( $P_{21}$ ) corresponds to the Altes distribution’s perfect localization for hyperbolic FM chirps ( $P_{22}$ ). This one-to-one correspondence between the Cohen and Hyperbolic classes greatly facilitates their analysis and gives alternative methods for calculating various TFRs.

### 4.3.4 $\kappa$ th Power Class

The Power class of TFRs consists of all TFRs that are scale covariant and power time-shift covariant, that is,

$$PC_Y^{(\kappa)}(t, f) = PC_X^{(\kappa)} \left( t - c \frac{d}{df} \xi(f/f_r), f \right) \quad \text{for } Y(f) = e^{-j2\pi \alpha \xi_\kappa(f/f_r)} X(f) \tag{4.20}$$

where  $\xi_\kappa(f) = \text{sgn}(f)|f|^\kappa$ , for  $\kappa \neq 0$  [Hlawatsch et al., 1993]. Consequently, the  $\kappa$ th Power class perfectly represents group delay changes in the signal that are powers of frequency. When  $\kappa = 1$ , the Power class

is equivalent to the Affine class. The central member,  $AM^{(\kappa)}$  in Table 4.1, is the Power class equivalent to the Altes-Marinovic distribution.

## 4.4 Common TFRs and Their Use in Biomedical Applications

This section will briefly review some of the TFRs commonly used in biomedical analysis and summarize their relative advantages and disadvantages.

### 4.4.1 Wigner Distribution

One of the oldest TFRs in Table 4.1 is the Wigner distribution (WD), which Wigner proposed in quantum mechanics as a two-dimensional statistical distribution relating the Fourier transform pairs of position and momentum of a particle. Table 4.3 reveals that the WD satisfies a large number of desirable TFR properties,  $P_1$  to  $P_3$ ,  $P_5$  to  $P_7$ ,  $P_9$  to  $P_{21}$ , and  $P_{23}$  and  $P_{25}$ . It is a member of both the Cohen and the Affine classes. The WD is a high-resolution TFR for linear FM chirps, sinusoids, and impulses. Since the WD satisfies Moyal's formula, it has been used to design optimal signal-detection and synthesis algorithms. The drawbacks of the WD are that it can be negative, it requires the signal to be known for all time, and it is a quadratic TFR with no implicit smoothing to remove cross-terms.

### 4.4.2 Smoothed Wigner Distributions

Many TFRs are related to the WD by either smoothing or a warping, for example, see Equation 4.8 and Equation 4.18 and Table 4.5. An intuitive understanding of the effects of cross-terms on quadratic TFRs can be obtained by analyzing the WD of a multicomponent signal  $y(t)$  in Equation 4.5 under the assumption that each signal component is a shifted version of a basic envelope, that is,  $x_n(t) = x(t - t_n) e^{2\pi f_n t}$ :

$$\begin{aligned} WD_y(t, f) &= \sum_{n=1}^N WD_x(t - t_n, f - f_n) \\ &+ 2 \sum_{k=1}^{N-1} \sum_{q=k+1}^N WD_x(t - \bar{t}_{k,q}, f - \bar{f}_{k,q}) \cos(2\pi [\Delta f_{k,q}(t - \Delta t_{k,q}) \\ &- \Delta t_{k,q}(f - \Delta f_{k,q}) + \Delta f_{k,q} \Delta t_{k,q}]) \end{aligned} \quad (4.21)$$

where  $\Delta f_{k,q} = f_k - f_q$  is the difference or "beat" frequency and  $\bar{f}_{k,q} = (f_k + f_q)/2$  is the average frequency between the  $k$ th and  $q$ th signal components. Similarly,  $\Delta t_{k,q}$  is the difference time and  $\bar{t}_{k,q}$  is the average time. The auto-WD terms in the first summation properly reflect the fact that the WD is a member of Cohen's shift covariant class. Unfortunately, the cross-WD terms in the second summation occur midway in the time-frequency plane between each pair of signal components and oscillate with a spatial frequency proportional to the distance between them. The Pseudo-WD (PWD) and the smoothed PWD (SPWD) defined in Table 4.1 use low-pass smoothing windows  $\eta(\tau)$  and  $\gamma(t)$  to reduce oscillatory cross-components. However, Table 4.5 reveals that the Pseudo-WD performs smoothly only in the frequency direction. Short smoothing windows greatly reduce the limit of integration in the PWD and SPWD formulations and hence reduce computation time. However, Table 4.3 reveals that smoothing the WD reduces the number of desirable properties it satisfies from 18 to 7 for the PWD and to only 3 for the SPWD.

### 4.4.3 Spectrogram

One of the most commonly used TFRs for slowly time-varying or quasi-stationary signals is the spectrogram, defined in Table 4.1 and Table 4.5 [Rabiner and Schafer, 1978]. It is equal to the squared magnitude

of the short-time Fourier transform, performing a local or “short-time” Fourier analysis by using a sliding analysis window  $\gamma(t)$  to segment the signal into short sections centered near the output time  $t$  before computing a Fourier transformation. The spectrogram is easy to compute, using either FFTs or a parallel bank of filters, and it is often easy to interpret. The quadratic spectrogram smooths away all cross-terms except those which occur when two signal components overlap. This smoothing also distorts auto-terms. The spectrogram does a poor job representing rapidly changing spectral characteristics or resolving two closely spaced components because there is an inherent tradeoff between good time resolution, which requires a short analysis window, and good frequency resolution, which requires a long analysis window. The spectrogram satisfies only three TFR properties listed in Table 4.2 and Table 4.3; that is, it is a nonnegative number of Cohen’s shift invariant class.

#### 4.4.4 Choi–Williams Exponential and Reduced Interference Distributions

The Choi–Williams exponential distribution (CWD) and the reduced interference distribution (RID) in Table 4.1 are often used as a compromise between the high-resolution but cluttered WD versus the smeared but easy to interpret spectrogram [Jeong and Williams, 1992; Williams and Jeong, 1991]. Since they are members of both Cohen’s class and the Affine class, their AF domain kernels in Table 4.4 have a very special form, that is,  $\Psi_C(\tau, \nu) = S_c(\tau\nu)$ , called a *product kernel*, which is a one-dimensional kernel evaluated at the product of its time–frequency variables [Hlawatsch and Boudreaux-Bartels, 1992]. The CWD uses a Gaussian product kernel in the AF plane to reduce cross-terms, while the RID typically uses a classic window function that is time-limited and normalized to automatically satisfy many desirable TFR properties (see Table 4.3). The CWD has one scaling factor  $\sigma$  that allows the user to select either good cross-term reduction or good auto-term preservation but, unfortunately, not always both. The generalized exponential distribution in Table 4.1 is an extension of the CWD that permits both [Hlawatsch and Boudreaux-Bartels, 1992]. Because the CWD and RID product kernels have hyperbolic isocontours in the AF plane, they always pass cross-terms between signal components that occur at either the same time or frequency, and they can distort auto-terms of linear FM chirp signals whose instantaneous frequency has a slope close to 1. The multiform tiltable exponential distribution (MTED) [Costa and Boudreaux-Bartels, 1994], another extension of the CWD, works well for any linear FM chirp.

#### 4.4.5 Scalogram or Wavelet Transform Squared Magnitude

The scalogram [Flandrin, 1993], defined in Table 4.1 and Table 4.5, is the squared magnitude of the recently introduced wavelet transform (WT) [Daubechies, 1992; Meyer, 1993] and is a member of the Affine class. It uses a special sliding analysis window  $\gamma(t)$ , called the *mother wavelet*, to analyze local spectral information of the signal  $x(t)$ . The mother wavelet is either compressed or dilated to give a multiresolution signal representation. The scalogram can be thought of as the multiresolution output of a parallel bank of octave band-filters. High-frequency regions of the WT domain have very good time resolution, whereas low-frequency regions of the WT domain have very good spectral resolution. The WT has been used to model the middle- to high-frequency range operation of the cochlea, to track transients such as speech pitch and the onset of the QRS complex in ECG signals, and to analyze fractal and chaotic signals. One drawback of the scalogram is its poor temporal resolution at low-frequency regions of the time-frequency plane and poor spectral resolution at high frequencies. Moreover, many “classic” windows do not satisfy the conditions needed for a mother wavelet. The scalogram cannot remove cross-terms when signal components overlap. Further, many discrete WT implementations do not preserve the important time-shift covariance property.

#### 4.4.6 Biomedical Applications

The electrocardiogram (ECG) signal is a recording of the time-varying electric rhythm of the heart. The short-duration QRS complex is the most predominant feature of the normal ECG signal. Abnormal heart rhythms can be identified on the ECG by detecting the QRS complex from one cycle to the next.

The transient detection capability of the wavelet transform (WT) has been exploited for detection of the QRS complex by Kadambe et al. [1992] and Li and Zheng [1993]. The WT exhibits local maxima which align across successive (dyadic) scales at the location of transient components, such as QRS complexes. The advantage of using the WT is that it is robust both to noise and to nonstationarities in the QRS complex.

Other pathologic features in the heart's electrical rhythm that appear only in high-resolution signal-averaged ECG signals are ventricular late potentials (VLPs). VLPs are small-amplitude, short-duration components that occur after the QRS complex and are precursors of dangerous, life-threatening cardiac arrhythmias. Tuteur [1989] used the peak of the WT at a fixed scale to identify simulated VLPs. More recently, Jones et al. [1992] compared different time-frequency techniques, such as the spectrogram, short-time spectral estimators, the smoothed WD, and the WT, in their ability to discriminate between normal patients and patients susceptible to dangerous arrhythmias. Morlet et al. [1993] used the transient detection capability of the WT to identify VLPs.

The WT has also been applied to the ECG signal in the context of ECG analysis and compression by Crowe et al. [1992]. Furthermore, Crowe et al. [1992] exploited the capability of the WT to analyze fractal-like signals to study heart rate variability (HRV) data, which have been described as having fractal-like properties.

The recording of heart sounds, or phonocardiogram (PCG) signal, has been analyzed using many time-frequency techniques. Bulgrin et al. [1993] compared the short-time Fourier transform and the WT for the analysis of abnormal PCGs. Picard et al. [1991] analyzed the sounds produced by different prosthetic valves using the spectrogram. The binomial RID, which is a fast approximation to the CWD, was used to analyze the short-time, narrow-bandwidth features of first heart sound in mongrel dogs by Wood et al. [1992].

TFRs have also been applied to nonstationary brain wave signals, including the electrocardiogram (EEG), the electrocorticogram (ECoG), and evoked potentials (EPs). Zaveri et al. [1992] used the spectrogram, the WD, and the CWD to characterize the nonstationary behavior of the ECoG of epileptic patients. Of the three techniques, the CWD exhibited superior results. The WT was used to identify the onset of epileptic seizures in the EEG by Schiff and Milton [1993], to extract a single EP by Bartnik et al. [1992], and to characterize changes in somatosensory EPs due to brain injury caused by oxygen deprivation by Thakor et al. [1993].

Crackles are lung sounds indicative of pathologic conditions. Verreault [1989] used AR models of slices of the WD to discriminate crackles from normal lung sounds.

The electrogastrogram (EGG) is a noninvasive measure of the time-varying electrical activity of the stomach. Promising results regarding abnormal EGG rhythms and the frequency of the EGG slow wave were obtained using the CWD by Lin and Chen [1994].

Widmalm et al. [1991] analyzed temporomandibular joint (TMJ) clicking using the spectrogram, the WD, and the RID. The RID allowed for better time-frequency resolution of the TMJ sounds than the spectrogram while reducing the cross-terms associated with the WD. TMJ signals were also modeled using nonorthogonal Gabor logons by Brown et al. [1994]. The primary advantage of this technique, which optimizes the location and support of each Gabor log-on, is that only a few such logons were needed to represent the TMJ clicks.

Auditory applications of TFRs are intuitively appealing because the cochlea exhibits constant-bandwidth behavior at low frequencies and constant-Q behavior at middle to high frequencies. Applications include a wavelet-based model of the early stages of acoustic signal processing in the auditory system [Yang et al., 1992], a comparison of the WD and Rihacek distribution on the response of auditory neurons to wideband noise stimulation [Eggermont and Smith, 1990], and spectrotemporal analysis of dorsal cochlear neurons in the guinea pig [Backoff and Clopton, 1992].

The importance of mammography, x-ray examination of the breast, lies in the early identification of tumors. Kaewlium and Longbotham [1993] used the spectrogram with a Gabor window as a texture discriminator to identify breast masses. Recently, a mammographic feature-enhancement technique using the WT was proposed by Laine et al. [1993]. The wavelet coefficients of the image are modified and then

reconstructed to the desired resolution. This technique enhanced the visualization of mammographic features of interest without additional cost or radiation.

Magnetic resonance imaging (MRI) allows for the imaging of the soft tissues in the body. Weaver et al. [1992] reduced the long processing time of traditional phase encoding of MRI images by WT encoding. Moreover, unlike phase-encoded images, Gibb's ringing phenomena and motion artifacts are localized in WT encoded images.

The Doppler ultrasound signal is the reflection of an ultrasonic beam due to moving red blood cells and provides information regarding blood vessels and heart chambers. Doppler ultrasound signals in patients with narrowing of the aortic valve were analyzed using the spectrogram by Cloutier et al. [1991]. Guo and colleagues [1994] examined and compared the application of five different time–frequency representations (the spectrogram, short-time AR model, CWD, RID, and Bessel distributions) with simulated Doppler ultrasound signals of the femoral artery. Promising results were obtained from the Bessel distribution, the CWD, and the short-time AR model.

Another focus of bioengineering applications of TFRs has concerned the analysis of biologic signals of interest, including the sounds generated by marine mammals, such as dolphins and whales, and the sonar echolocation systems used by bats to locate and identify their prey. The RID was applied to sperm whale acoustic signals by Williams and Jeong [1991] and revealed an intricate time-frequency structure that was not apparent in the original time-series data. The complicated time-frequency characteristics of dolphin whistles were analyzed by Tyack et al. [1992] using the spectrogram, the WD, and the RID, with the RID giving the best results. Flandrin [1988] analyzed the time-frequency structure of the different signals emitted by bats during hunting, navigation, and identifying prey using the smoothed Pseudo-WD. In addition, the instantaneous frequency of the various signals was estimated using time-frequency representations. Saillant et al. [1993] proposed a model of the bat's echolocation system using the spectrogram. The most common application of the spectrogram is the analysis and modification of quasi-stationary speech signals [Rabiner and Schafer, 1978].

## Acknowledgments

The authors would like to acknowledge the use of the personal notes of Franz Hlawatsch and Antonia Papandreou on TFR kernel constraints as well as the help given by Antonia Papandreou in critiquing the article and its tables.

## Further Information

Several TFR tutorials exist on the Cohen class [Boashash, 1991; Cohen, 1989; Flandrin, 1993; Hlawatsch and Boudreaux-Bartels, 1992], Affine class [Bertrand chapter in Boashash, 1991; Flandrin, 1993], hyperbolic class [Papandreou et al., 1993], and power class [Hlawatsch et al., 1993]. Several special conferences or issues of IEEE journals devoted to TFRs and the WT include Proc. of the IEEE-SP Time Frequency and Time-Scale Workshop, 1992, *IEEE Sig. Proc. Soc.*; Special issue on wavelet transforms and multiresolution signal analysis, *IEEE Trans. Info. Theory*, 1992; and Special issue on wavelets and signal processing, *IEEE Trans. SP*, 1993. An extended list of references on the application of TFRs to problems in biomedical or bio-engineering can be found in Murray [1994].

Signals recorded from the human body provide information pertaining to its organs. Their characteristic shape, or temporal and spectral properties, can be correlated with normal or pathological functions. In response to dynamical changes in the function of these organs, the signals may exhibit time-varying as well as nonstationary responses. Time–frequency and time-scale analysis techniques are well suited for such biological signals. Joint time-frequency signal analysis techniques include short-term Fourier transform and Wigner–Ville distribution, and related reduced interference distribution. Joint time-scale analysis includes continuous and discrete, orthonormal and non-orthonormal wavelets. These techniques find applications in the analysis of transient and time-varying events in biological signals. Examples of applications include cardiac signals (for detection of ischemia and reperfusion-related changes in QRS complex, and late potentials in ECG) and neurological signals (evoked potentials and seizure spikes).

## 5.1 Introduction

---

Digital signal processing uses sophisticated mathematical analysis and algorithms to extract information hidden in signals derived from sensors. In biomedical applications these sensors such as electrodes, accelerometers, optical imagers, etc., record signals from biological tissue with the goal of revealing their health and well-being in clinical and research settings. Refining those signal processing algorithms for biological applications requires building suitable signal models to capture signal features and components that are of diagnostic importance. As most signals of a biological origin are time-varying, there is a special need for capturing transient phenomena in both healthy and chronically ill states.

A critical feature of many biological signals is frequency domain parameters. Time localization of these changes is an issue for biomedical researchers who need to understand subtle frequency content changes over time. Certainly, signals marking the transition from severe normative to diseased states of an organism sometimes undergo severe changes which can easily be detected using methods such as the Short Time Fourier Transform (STFT) for deterministic signals and its companion, the spectrogram, for power signals. The basis function for the STFT is a complex sinusoid,  $e^{j2\pi ft}$ , which is suitable for stationary analyses of narrowband signals. For signals of a biological origin, the sinusoid may not be a suitable analysis signal. Biological signals are often spread out over wide areas of the frequency spectrum. Also as Rioul and Vetterli [1] point out, when the frequency content of a signal changes in a rapid fashion, the frequency content becomes smeared over the entire frequency spectrum as it does in the case of the onset of seizure spikes in epilepsy or a fibrillating heartbeat as revealed on an ECG. The use of a narrowband basis function does not accurately represent wideband signals. It is preferred that the basis functions be similar to the signal under study. In fact, for a compact representation using as few basis functions as possible, it is desirable to use basis functions that have a wider frequency spread as most biological signals do. Wavelet theory, which provides for wideband representation of signals [2–4], is therefore a natural choice for biomedical engineers involved in signal processing and currently under intense study [5–9].

## 5.2 The Wavelet Transform: Variable Time and Frequency Resolution

---

### 5.2.1 Continuous Wavelet Transform

A decomposition of a signal, based on a wider frequency mapping and consequently better time resolution is possible with the wavelet transform. The Continuous Wavelet Transform (CWT) [3] is defined thusly for a continuous signal,  $x(t)$ ,

$$\text{CWT}_x(\tau, a) = \frac{1}{\sqrt{a}} \int x(at)g^*\left(\frac{t-\tau}{a}\right) dt \quad (5.1a)$$

or with change of variable as

$$\text{CWT}_x(\tau, a) = \sqrt{a} \int x(at)g^*\left(t - \frac{\tau}{a}\right) dt \quad (5.1b)$$

where  $g(t)$  is the mother or basic wavelet,  $*$  denotes a complex conjugate,  $a$  is the scale factor, and  $t$  is a time shift. Typically,  $g(t)$  is a bandpass function centered around some center frequency,  $f_0$ . Scale  $a$  allows the compression or expansion of  $g(t)$  [1,3,10]. A larger scale factor generates the same function compressed in time whereas a smaller scale factor generates the opposite. When the analyzing signal is contracted in time, similar signal features or changes that occur over a smaller time window can be studied. For the wavelet transform, the same basic wavelet is employed with only alterations in this signal arising from scale changes. Likewise, a smaller scale function enables larger time translations or delays in the basic signal.

The notion of scale is a critical feature of the wavelet transform because of time and frequency domain reciprocity. When the scale factor,  $a$ , is enlarged, the effect on frequency is compression as the analysis window in the frequency domain is contracted by the amount  $1/a$  [10]. This equal and opposite frequency domain scaling effect can be put to advantageous use for frequency localization. Since we are using bandpass filter functions, a center frequency change at a given scale yields wider or narrower frequency response changes depending on the size of the center frequency. This is the same in the analog or digital filtering theories as “constant-Q or quality factor” analysis [1,10,11]. At a given Q or scale factor, frequency translates are accompanied by proportional bandwidth or resolution changes. In this regard, wavelet transforms are often written with the scale factor rendered as

$$a = \frac{f}{f_0} \quad (5.2)$$

or

$$\text{CWT}_x \left( \tau, a = \frac{f}{f_0} \right) = \frac{1}{\sqrt{f/f_0}} \int x(t) g^* \left( \frac{t - \tau}{f/f_0} \right) dt \quad (5.3)$$

This is the equivalent to logarithmic scaling of the filter bandwidth or octave scaling of the filter bandwidth for power-of-two growth in center frequencies. Larger center frequency entails a larger bandwidth and vice versa.

The analyzing wavelet,  $g(t)$ , should satisfy the following conditions:

1. Belong to L2 (R), that is, be square integrable (be of finite energy) [2]
2. Be analytic [ $G(\omega) = 0$  for  $\omega < 0$ ] and thus be complex-valued. In fact many wavelets are real-valued; however, analytic wavelets often provide valuable phase information [3], indicative of changes of state, particularly in acoustics, speech, and biomedical signal processing [8]
3. Be admissible. This condition was shown to enable invertibility of the transform [2,6,12]:

$$s(t) = \frac{1}{c_g} \int_{-\infty}^{\infty} \int_{a>0}^{\infty} W(\tau, a) \frac{1}{\sqrt{a}} g \left( \frac{t - \tau}{a} \right) \frac{1}{a^2} da d\tau \quad (5.3a)$$

where  $c_g$  is a constant that depends only on  $g(t)$  and  $a$  is positive. For an analytic wavelet the constant should be positive and convergent:

$$c_g = \int_0^{\infty} \frac{|G(\omega)|^2}{\omega} d\omega < \infty \quad (5.3b)$$

which in turn imposes an admissibility condition on  $g(t)$ . For a real-valued wavelet, the integrals from both  $-\infty$  to 0 and 0 to  $+\infty$  should exist and be greater than zero.

The admissibility condition along with the issue of reversibility of the transformation is not so critical for applications where the emphasis is on signal analysis and feature extraction. Instead, it is often more important to use a fine sampling of both the translation and scale parameters. This introduces redundancy which is typical for the CWT, unlike for the discrete wavelet transform, which is used in its dyadic, orthogonal, and invertible form.

All admissible wavelets with  $g \in L1(\mathbb{R})$  have no zero-frequency contribution. That is, they are of zero mean,

$$\int_{-\infty}^{+\infty} g(t) dt = 0 \quad (5.3c)$$

or equivalently  $G(\omega) = 0$  for  $\omega = 0$ , meaning that  $g(t)$  should not have nonzero DC [6,12]. This condition is often being applied also to nonadmissible wavelets.

The complex-valued Morlet's wavelet is often selected as the choice for signal analysis using the CWT. Morlet's wavelet [3] is defined as

$$g(t) = e^{j2\pi f_0 t} e^{-(t^2/2)} \quad (5.4a)$$

with its scaled version written as

$$g\left(\frac{t}{a}\right) = e^{j(2\pi f_0/a)t} e^{-(t^2/2a^2)} \quad (5.4b)$$

Morlet's wavelet insures that the time-scale representation can be viewed as a time-frequency distribution as in Equation 5.3. This wavelet has the best representation in both time and frequency because it is based on the Gaussian window. The Gaussian function guarantees a minimum time-bandwidth product, providing for maximum concentration in both time and frequency domains [1]. This is the best compromise for a simultaneous localization in both time and frequency as the Gaussian function's Fourier transform is simply a scaled version of its time domain function. Also the Morlet wavelet is defined by an explicit function and leads to a quasi continuous discrete version [11]. A modified version of Morlet's wavelet leads to fixed center frequency,  $f_0$ , with width parameter,  $s$ ,

$$g(\sigma, t) = e^{j2\pi f_0 t} e^{-(t^2/2\sigma^2)} \quad (5.4c)$$

Once again time–frequency (TF) reciprocity determines the degree of resolution available in time and frequency domains. Choosing a small window size,  $s$ , in the time domain, yields poor frequency resolution while offering excellent time resolution and vice versa [11,13]. To satisfy the requirement for admissibility and  $G(0) = 0$ , a correction term must be added. For  $\omega > 5$ , this correction term becomes negligibly small and can be omitted. The requirements for the wavelet to be analytic and of zero mean is best satisfied for  $\omega_0 = 5.3$  [3].

Following the definition in Equation 5.1a and Equation 5.1b the discrete implementation of the CWT in the time-domain is a set of bandpass filters with complex-valued coefficients, derived by dilating the basic wavelet by the scale factor,  $a$ , for each analyzing frequency. The discrete form of the filters for each  $a$  is the convolution:

$$S(k, a) = \frac{1}{\sqrt{a}} \sum_{i=k-(\pi/2)}^{k+(\pi/2)} s(i)g_m * \left(\frac{i-k}{a}\right) = \frac{1}{\sqrt{a}} \sum_{i=-(\pi/2)}^{\pi/2} s(k-i)g_m * \left(\frac{i}{a}\right) \quad (5.4d)$$

with  $k = t/T_s$ , where  $T_s$  is the sampling interval. The summation is over a number of terms,  $n$ . Because of the scaling factor  $a$  in the denominator of the argument of the wavelet, the wavelet has to be resampled at a sampling interval  $T_s/a$  for each scale  $a$ . Should the CWT cover a wide frequency range, a computational problem would arise. For example, if we wish to display the CWT over 10 octaves (a change by one octave corresponds to changing the frequency by a factor of 2), the computational complexity (size of the summation) increases by a factor of  $2^{10} = 1024$ . The algorithm by Holschneider et al. [14] solves this problem for certain classes of wavelets by replacing the need to resample the wavelet with a recursive application of an interpolating filter. Since scale is a multiplicative rather than an additive parameter, another way of reducing computational complexity would be by introducing levels between octaves (voices) [15]. Voices are defined to be the scale levels between successive octaves, uniformly distributed in a multiplicative sense [13,16]. Thus, the ratio between two successive voices is constant. For example, if one wishes to have ten voices per octave, then the ratio between successive voices is 21/10. The distance between two levels, ten voices apart is an octave.

The CWT can also be implemented in the frequency domain. Equation 5.1 may be formulated in the frequency domain as:

$$\text{CWT}(\tau, a) = \sqrt{a} \int S(\omega) G * (a\omega) e^{j\omega\tau} d\omega \quad (5.5)$$

where  $S(\omega)$  and  $G(\omega)$  denote the Fourier transformed  $s(t)$  and  $g(t)$ , and  $j = (-1)^{1/2}$ . The analyzing wavelet  $g(t)$  generally has the following Fourier transform:

$$G_{\tau,u}(\omega) = \sqrt{a} G(a\omega) e^{j\omega\tau} \quad (5.6a)$$

The Morlet wavelet [Equation 5.4a and Equation 5.4b] in frequency domain is a Gaussian function:

$$G_m(\omega) = \frac{1}{\sqrt{2\omega}} e^{-(\omega-\omega_0)^2/2} \quad (5.6b)$$

From Equation 5.6a and Equation 5.6b it can be seen that for low frequencies,  $\omega$ , (larger scales  $a$ ) the width,  $D/\omega$ , of the Gaussian is smaller and vice versa. In fact, the ratio  $D\omega/\omega$  is constant [1], that is, Morlet wavelets may be considered filter banks of the constant-Q factor.

Based on Equation 5.5, Equation 5.6a, and Equation 5.6b the wavelet transform can be implemented in the frequency domain. At each scale, the Fourier image of the signal can be computed as

$$Y(\omega, a) = S(\omega) \bullet G_m(\omega, a) \quad (5.6c)$$

with  $S(\omega)$  being the Fourier transform of the signal,  $G_m(\omega, a)$  being the scaled Fourier image of the Morlet wavelet at scale  $a$ , and the operation  $\bullet$  standing for element-by-element multiplication (windowing in frequency domain). The signal at each scale  $a$  will finally be obtained by applying the inverse Fourier transform:

$$\text{CWT}(\tau, a) = (\text{FFT})^{-1} Y(\omega, a) \quad (5.6d)$$

This approach has the advantage of avoiding computationally intensive convolution of time-domain signals by using multiplication in the frequency domain, as well as the need of resampling the mother wavelet in the time domain [17,18].

Note that the CWT is, in the general case, a complex-valued transformation. In addition to its magnitude, its phase often contains valuable information pertinent to the signal being analyzed, particularly in instants of transients [3]. Sometimes the TF distribution of the nonstationary signal is much more important. This may be obtained by means of real-valued wavelets. Alternatives to the complex-valued Morlet wavelet are simpler, real-valued wavelets that may be utilized for the purpose of the CWT. For example, the early Morlet wavelet, as used for seismic signal analysis [19], had the following real-valued form:

$$g(t) = \cos(5t) e^{-t^2/2} \quad (5.6e)$$

It had a few cycles of a sine wave tapered by a Gaussian envelope. Though computationally attractive, this idea contradicts the requirement for an analytic wavelet, that is, its Fourier transform  $G(\omega) = 0$  for  $\omega < 0$ . An analytic function is generally complex-valued in the time domain and has its real and imaginary parts as Hilbert transforms of each other [2,20]. This guarantees only positive-frequency components of the analyzing signal.

A variety of analyzing wavelets have been proposed in recent years for time-scale analysis of the ECG. For example, Senhadji et al. [21] applied a pseudo-Morlet’s wavelet to bandpass filtering to find out whether some abnormal ECG events like extrasystoles and ischemia are mapped on specific decomposition levels:

$$g(t) = C(1 + \cos(2\pi f_0 t))e^{-2i\pi k f_0 t} \quad t \leq 1/2f_0 \quad \text{and} \quad k \text{ integer} \notin \{-1, 0, 1\} \quad (5.6f)$$

with the product  $kf_0$  defining the number of oscillations of the complex part, and  $C$  representing a normalizing constant such that  $\|g\| = 1$ . The above function is a modulated complex sine wave that would yield complex-valued CWT including phase information. However its envelope is a cosine, rather than a Gaussian, as in the case of the complex Morlet wavelet. It is well known that strictly the Gaussian function (both in time and frequency domain) guarantees the smallest possible time-bandwidth product which means maximum concentration in the time and frequency domains [22].

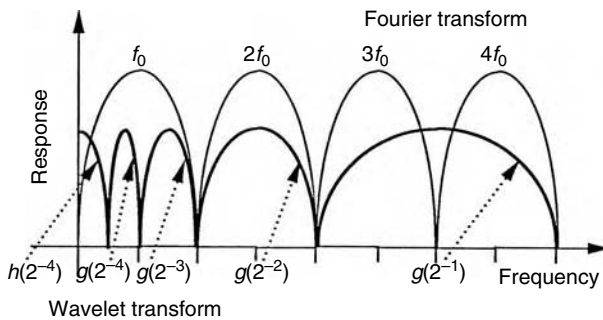

The STFT has the same time-frequency resolution regardless of frequency translations. The STFT can be written as

$$\text{STFT}(\tau, f) = \int_{-\infty}^{\infty} x(t)g * (t - \tau)e^{-2\pi jft} dt \quad (5.7)$$

where  $g(t)$  is the time window that selects the time interval for analysis or otherwise known as the spectrum localized in time. Figure 5.1 shows comparative frequency resolution of both the STFT as well as the wavelet transform. The STFT is often thought to be analogous to a bank of bandpass filters, each shifted by a certain modulation frequency,  $f_0$ . In fact, the Fourier transform of a signal can be interpreted as passing the signal through multiple bandpass filters with impulse response,  $g(t)e^{j2\pi ft}$ , and then using complex demodulation to downshift the filter output. Ultimately, the STFT as a bandpass filter rendition simply translates the same low pass filter function through the operation of modulation. The characteristics of the filter stay the same though the frequency is shifted.

Unlike the STFT, the wavelet transform implementation is not frequency independent so that higher frequencies are studied with analysis filters with wider bandwidth. Scale changes are not equivalent to varying modulation frequencies that the STFT uses. The dilations and contractions of the basis function allow for variation of time and frequency resolution instead of uniform resolution of the Fourier transform [15].

Both the wavelet and Fourier transform are linear time–frequency representations (TFRs) for which the rules of superposition or linearity apply [10]. This is advantageous in cases of two or more separate signal constituents. Linearity means that cross-terms are not generated in applying either the linear TF or time-scale operations. Aside from linear TFRs, there are quadratic TF representations which are quite useful in displaying energy and correlation domain information. These techniques, also described elsewhere in this volume include the Wigner–Ville distribution (WVD), smoothed WVD, the reduced inference

**FIGURE 5.1** Comparative frequency resolution for STFT and WT. Note that frequency resolution of STFT is constant across frequency spectrum. The WT has a frequency resolution that is proportional to the center frequency of the bandpass filter.

distribution (RID), etc. One example of the smoothed Wigner-Ville distribution is

$$W(t, f) = \int s * \left( t - \frac{1}{2} \tau \right) e^{-j\tau 2\pi f} s * \left( t + \frac{1}{2} \tau \right) h \left( \frac{\tau}{2} \right) d\tau \quad (5.8a)$$

where  $h(t)$ , is a smoothing function. In this case the smoothing kernel for the generalized or Cohen's class of TFRs is

$$\phi(t, \tau) = h \left( \frac{\tau}{2} \right) \delta(t) \quad (5.8b)$$

These methods display joint TF information in such a fashion as to display rapid changes of energy over the entire frequency spectrum. They are not subject to variations due to window selection as in the case of the STFT. A problematic area for these cases is the elimination of those cross-terms that are the result of the embedded correlation.

It is to be noted that the scalogram or scaled energy representation for wavelets can be represented as a WVD as [1]

$$|\text{CWT}_x(\tau, a)|^2 = \iint W_x(u, n) W_g^* \left( \frac{u - t}{a}, an \right) dudn \quad (5.9a)$$

where

$$W_x(t, f) = \int x * \left( t - \frac{1}{2} \tau \right) e^{-j\tau 2\pi f} x * \left( t + \frac{1}{2} \tau \right) d\tau \quad (5.9b)$$

## 5.2.2 The Discrete Wavelet Transform

In the discrete TFRs both time and scale changes are discrete. Scaling for the discrete wavelet transform involves sampling rate changes. A larger scale corresponds to subsampling the signal. For a given number of samples a larger time swath is covered for a larger scale. This is the basis of signal compression schemes as well [23]. Typically, a dyadic or binary scaling system is employed so that given a discrete wavelet function,  $y(x)$ , is scaled by values that are binary. Thus

$$\psi_{2^j}(t) = 2^j \psi(2^j t) \quad (5.10a)$$

where  $j$  is the scaling index and  $j = 0, -1, -2, \dots$  In a dyadic scheme, subsampling is always decimation-in-time by a power of 2. Translations in time will be proportionally larger as well as for a more sizable scale.

It is for discrete time signals that scale and resolution are related. When the scale is increased, resolution is lowered. Resolution is strongly related to frequency. Subsampling means lowered frequency content. Rioul and Vetterli [1] use the microscope analogy to point out that smaller scale (higher resolution) helps to explore fine details of a signal. This higher resolution is apparent with samples taken at smaller time intervals.

## 5.3 A Multiresolution Theory: Decomposition of Signals

### 5.3.1 Using Orthogonal Wavelets

One key result of the wavelet theory is that signals can be decomposed in a series of orthogonal wavelets. This is similar to the notion of decomposing a signal in terms of discrete Fourier transform components or Walsh or Haar functions. Orthogonality insures a unique and complete representation of the signal.

Likewise the orthogonal complement provides some measure of the error in the representation. The difference in terms of wavelets is that each of the orthogonal vector spaces offers component signals with varying levels of resolution and scale. This is why Mallat [24] named his algorithm the multiresolution signal decomposition. Each stage of the algorithm generates wavelets with sequentially finer representations of signal content. To achieve an orthogonal wavelet representation, a given wavelet function,  $f(t)$ , at a scaling index level equal to zero, is first dilated by the scale coefficient  $2^j$ , then translating it by  $2^{-j}n$  and normalizing by gives:

$$\sqrt{2^{-j}}\phi_{2^j}(t - 2^{-j}n) \quad (5.10b)$$

The algorithm begins with an operator  $A_{2^j}$  for discrete signals that takes the projections of a signal,  $f(t)$  onto the orthonormal basis,  $V_{2^j}$ :

$$A_{2^j}f(t) = 2^{-j} \sum_{n=-\infty}^{\infty} \langle f(u), \phi_{2^j}(u - 2^{-j}n) \rangle \phi_{2^j}(t - 2^{-j}n) \quad (5.11)$$

where  $2^j$  defines the level of resolution.  $A_{2^j}$  is defined as the multi-resolution operator that approximates a signal at a resolution  $2^j$ . Signals at successively lower resolutions can be obtained by repeated application of the operator  $A_{2^j}(-J \leq j \leq -1)$ , where  $J$  specifies the maximum resolution, such that  $A_{2^j}f(x)$  is the closest approximation of function  $f(x)$  at resolution  $2^j$ . Here we note that  $\langle \rangle$  is simply a convolution defined thusly,

$$\langle f(u), \phi_{2^j}(u - 2^{-j}n) \rangle = \int_{-\infty}^{\infty} f(u)\phi(u - 2^{-j}n)du \quad (5.12)$$

Here  $f(x)$  is the impulse response of the scaling function. The Fourier transforms of these functions are lowpass filter functions with successively smaller halfband lowpass filters. This convolution synthesizes the coarse signal at a resolution/scaling level  $j$ :

$$C_{2^j}f = \langle f(t), \phi_{2^j}(t - 2^{-j}n) \rangle \quad (5.13)$$

Each level  $j$  generates new basis functions of the particular orthonormal basis with a given discrete approximation. In this case, larger  $j$  provides for decreasing resolution and increasing the scale in proportional fashion for each level of the orthonormal basis. Likewise, each sequentially larger  $j$  provides for time shift in accordance with scale changes, as mentioned above, and the convolution or inner product operation generates the set of coefficients for the particular basis function. A set of scaling functions at decreasing levels of resolution,  $j = 0, -1, -2, \dots, -6$  is given in Reference 25.

The next step in the algorithm is the expression of basis function of one level of resolution,  $f^{2^j}$  by a higher resolution,  $f^{2^{j+1}}$ . In the same fashion as above, an orthogonal representation of the basis  $V^{2^j}$  in terms of  $V^{2^{j+1}}$  is possible, or

$$\phi_{2^j}(t - 2^{-j}n) = 2^{-j-1} \sum_{k=-\infty}^{\infty} \langle \phi_{2^j}(u - 2^{-j}n), \phi_{2^{j+1}}(u - 2^{-j-1}k) \rangle \phi_{2^{j+1}}(t - 2^{-j-1}k) \quad (5.14)$$

Here the coefficients are once again the inner products between the two basis functions. A means of translation is possible for converting the coefficients of one basis function to the coefficients of the basis

function at a higher resolution:

$$\begin{aligned} C_{2^j} f &= \langle f(u), \phi_{2^j}(t - 2^{-j}n) \rangle \\ &= 2^{-j-1} \sum_{k=-\infty}^{\infty} \langle \phi_{2^j}(u - 2^{-j}n), \phi_{2^{j+1}}(u - 2^{-j-1}k) \rangle \langle f(u), \phi_{2^{j+1}}(t - 2^{-j-1}k) \rangle \end{aligned} \quad (5.15)$$

Mallat [24] also conceives of the filter function,  $h(n)$ , whose impulse response provides this conversion, namely,

$$C_{2^j} f = \langle f(u), \phi_{2^j}(t - 2^{-j}n) \rangle = 2^{-j-1} \sum_{k=-\infty}^{\infty} \tilde{h}(2n - k) \langle f(u), \phi_{2^{j+1}}(t - 2^{-j-1}k) \rangle \quad (5.16)$$

where  $h(n) = 2^{-j-1} \cdot f_{2^j}(u - 2^{-j}n), f_{2^{j+1}}(u - 2^{-j-1}k)$  and  $\tilde{h}(n) = h(-n)$  is the impulse response of the appropriate mirror filter.

Using the tools already described, Mallat [24] then proceeds to define the orthogonal complement,  $O_2^j$  to the vector space  $V_2^j$  at resolution level  $j$ . This orthogonal complement to  $V_2^j$  is the error in the approximation of the signal in  $V_2^{j+1}$  by use of basis function belonging to the orthogonal complement. The basis functions of the orthogonal complement are called orthogonal wavelets,  $\psi(x)$ , or simply wavelet functions. To analyze finer details of the signal, a wavelet function derived from the scaling function is selected. The Fourier transform of this wavelet function has the shape of a bandpass filter in frequency domain. A basic property of the function  $\psi$  is that it can be scaled according to

$$\text{CWT}_x(\tau, a) = \frac{1}{\sqrt{a}} \int x(at) g * \left( \frac{t - \tau}{a} \right) dt \quad (5.16a)$$

An orthonormal basis set of wavelet functions is formed by dilating the function  $\psi(x)$  with a coefficient  $2^j$  and then translating it by  $2^{-j}n$ , and normalizing by  $\frac{1}{\sqrt{2^j}}$ . They are formed by the operation of convolving the scale function with the quadrature mirror filter

$$\psi(\omega) = G\left(\frac{\omega}{2}\right) \phi\left(\frac{\omega}{2}\right) \quad (5.16b)$$

where  $G(\omega) = e - j\omega - H(\omega + \pi)$  is the quadrature mirror filter transfer response and  $g(n) = (-1)^{n-1} n h(1 - n)$  is the corresponding impulse response function.

The set of scaling and wavelet functions presented here form a duality, together resolving the temporal signal into coarse and fine details, respectively. For a given level  $j$  then, this detail signal can once again be represented as a set of inner products:

$$D_{2^j} f = \langle f(t), \psi_{2^j}(x - 2^{-j}n) \rangle \quad (5.17)$$

For a specific signal,  $f(x)$ , we can employ the projection operator as before to generate the approximation to this signal on the orthogonal complement. As before, the detail signal can be decomposed using the higher resolution basis function:

$$\begin{aligned} D_{2^j} f &= \langle f(u), \psi_{2^j}(t - 2^{-j}n) \rangle \\ &= 2^{-j-1} \sum_{k=-\infty}^{\infty} \langle \psi_{2^j}(t - 2^{-j}n), \psi_{2^{j+1}}(u - 2^{-j-1}k) \rangle \langle f(u), \phi_{2^{j+1}}(t - 2^{-j-1}k) \rangle \end{aligned} \quad (5.18)$$

**FIGURE 5.2** Flow chart of a multiresolution algorithm showing how successive coarse and detail components of resolution level,  $j$ , are generated from higher resolution level,  $j + 1$ .

or in terms of the synthesis filter response for the orthogonal wavelet

$$D_{2^j} f = \langle f(u), \psi_{2^j}(t - 2^{-j}n) \rangle = 2^{-j-1} \sum_{k=-\infty}^{\infty} \tilde{g}(2n - k) \langle f(u), \phi_{2^{j+1}}(t - 2^{-j-1}k) \rangle \quad (5.19)$$

At this point, the necessary tools are here for a decomposition of a signal in terms of wavelet components, coarse and detail signals. Multiresolution wavelet description provides for the analysis of a signal into lowpass components at each level of resolution called coarse signals through the  $C$  operators. At the same time the detail components through the  $D$  operator provide information regarding bandpass components. With each decreasing resolution level, different signal approximations are made to capture unique signal features. Procedural details for realizing this algorithm follow.

### 5.3.2 Implementation of the Multiresolution Wavelet Transform: Analysis and Synthesis of Algorithms

A diagram of the algorithm for the multiresolution wavelet decomposition algorithm is shown in Figure 5.2. A step-by-step rendition of the analysis is as follows:

1. Start with  $N$  samples of the original signal,  $x(t)$ , at resolution level  $j = 0$ .
2. Convolve signal with original scaling function,  $f(t)$ , to find  $C1 f$  as in Equation 5.13 with  $j = 0$ .
3. Find coarse signal at successive resolution levels,  $j = -1, -2, \dots, -J$  through Equation 5.16; keep every other sample of the output.
4. Find detail signals at successive resolution levels,  $j = -1, -2, \dots, -J$  through Equation 5.19; keep every other sample of the output.
5. Decrease  $j$  and repeat steps 3 through 5 until  $j = -J$ .

Signal reconstruction details are presented in References 24 and 26.

## 5.4 Further Developments of the Wavelet Transform

Of particular interest are Daubechies' orthonormal wavelets of compact support with the maximum number of vanishing moments [27,28]. In these works, wavelets of very short length are obtained (number of coefficients 4, 6, 8, etc.) thus allowing for very efficient data compression.

Another important development of the multiresolution decomposition is the wavelet packet approach [29]. Instead of the simple multiresolution three-stage filter bank (low-pass/high-pass/downsampling) described previously in this chapter, wavelet packets analyse all subsystems of coefficients at all scale levels, thus yielding the full binary tree for the orthogonal wavelet transform, resulting in a completely

evenly spaced frequency resolution. The wavelet packet system gives a rich orthogonal structure that allows adaptation to particular signals or signal classes. An optimal basis may be found, minimizing some function on the signal sequences, on the manifold of orthonormal bases. Wavelet packets allow for a much more efficient adaptive data compression [30]. Karrakchou and Kunt report an interesting method of interference cancelling using a wavelet packet approach [8]. They apply “local” subband adaptive filtering by using a non-uniform filter bank, having a different filter for each subband (scale). Furthermore, the orthonormal basis has “optimally” been adapted to the spectral contents of the signal. This yields very efficient noise suppression without significantly changing signal morphology.

## 5.5 Applications

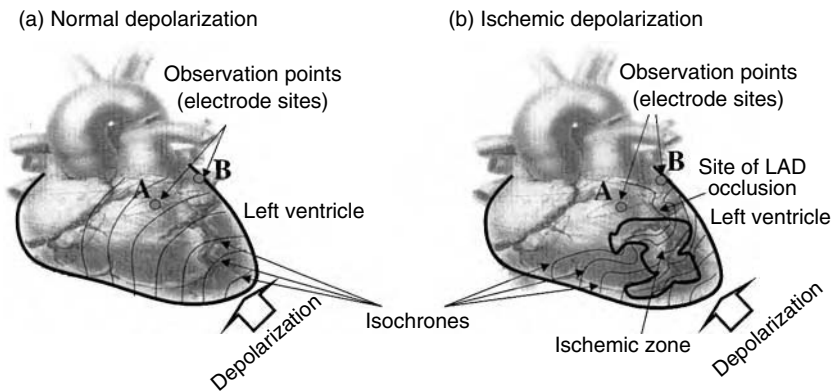

### 5.5.1 Cardiac Signal Processing

Signals from the heart, especially the ECG, are well suited for analysis by joint time-frequency and time-scale distributions. That is because the ECG signal has a very characteristic time-varying morphology, identified as the P-QRS-T complex. Throughout this complex, the signal frequencies are distributed (1) low frequency — P and T waves, (2) mid to high frequency — QRS complex [31,32]. Of particular diagnostic importance are changes in the depolarization (activation phase) of the myocardium, represented by the QRS complex. These changes cause alterations in the propagation of the depolarization wave detectable by time-frequency analysis of one-dimensional electrocardiographic signals recorded from the body surface. Two examples are presented below.

#### 5.5.1.1 Analysis of the QRS Complex Under Myocardial Ischemia

*Ischemia-related intra-QRS changes.* When the heart muscle becomes ischemic or infarcted, characteristic changes are seen in the form of elevation or depression of the ST-segment. Detection of these changes requires an extension of the signal bandwidth to frequencies down to 0.05 Hz and less, making the measurements susceptible to motion artifact errors. Ischemia also causes changes in conduction velocity and action potential duration, which results in fragmentation in the depolarization front (Figure 5.3) and appearance of low-amplitude notches and slurs in the body surface ECG signals. These signal changes are detectable with various signal processing methods [33,34]. Depolarization abnormalities due to ischemia may also cause arrhythmogenic reentry [35], which is one more reason to detect intra-QRS changes precisely.

Identification of ischemia-related changes in the QRS complex is not as well known, and interpretation of the QRS complex would be less susceptible to artifactual errors, as compared to the ST analysis. Thus,

**FIGURE 5.3** Idealized example of (a) normal propagation and (b) wavefront fragmentation due to an ischemic zone of slow conduction. The superimposed lines are isochrones, connecting points at which the depolarization arrives at the same time.

time-frequency or time-scale analysis would serve a useful function in localizing the ischemia-related changes within the QRS complex, but would be somewhat independent of the artifactual errors.

Experimental findings. In experimental animals, the response of the heart to coronary artery occlusion and then reperfusion was studied. The Left Anterior Descending (LAD) branch of the coronary artery was temporarily occluded for 20 min. Subsequent to that, the occlusion was removed, and resulting reperfusion more or less restored the ECG signal after 20 min. The coronary artery was occluded a second time for 60 min, and once again occlusion was removed and blood flow was restored. Single ECG cycles were analyzed using the continuous wavelet transform [33]. Figure 5.4 shows the time-scale plots for the ECG cycles for each of the five stages of this experiment. The three-dimensional plots give time in the P-QRS-T complex on one axis, the scale (or equivalent frequency) on another axis, and the normalized magnitude on the third axis. First occlusion results in a localized alteration around 100 ms and the midscale, which shows up as a bump in the three-dimensional plot or a broadening in the contour plot. Upon reperfusion, the time-scale plot returns to the pre-occlusion state. The second occlusion brings about a far more significant change in the time-scale plot, with increased response in the 0 to 200 msec and mid-scale ranges. This change is reversible. We were thus able to show, using time-scale technique, ischemia related changes in the QRS complex, and the effects of occlusion as well as reperfusion.

Potential role of ischemia-related intra-QRS changes in coronary angioplasty. The above results are also applicable to human ECGs and clinical cardiology. For example, a fairly common disorder is the occlusion of coronary vessels, causing cardiac ischemia and eventually infarction. An effective approach to the treatment of the occlusion injury is to open the coronary blood vessels using a procedure called coronary angioplasty (also known as percutaneous transluminal coronary angioplasty or PTCA). Vessels may be opened using a balloon-type or a laser-based catheter. When reperfusion occurs following the restoration of the blood flow, initially a reperfusion injury is known to occur (which sometimes leads to arrhythmias) [35]. The ST level changes as well, but its detection is not easy due to artifacts, common in a PTCA setting. In a clinical study, we analyzed ischemia and reperfusion changes before and after the PTCA procedure. Short-term occlusion and ischemia followed by reperfusion were carried out in a cardiac catheterization laboratory at the Johns Hopkins Hospital in connection with PTCA) [36]. Figure 5.5 shows time-scale plots of a patient derived from continuous wavelet transform. Characteristic midscale hump in the early stages of the QRS cycle is seen in the three-dimensional time-scale plot. Then, 60 min after angioplasty, the normal looking time-scale plot of the QRS complex is restored in this patient. This study suggests that time-scale analysis and resulting three-dimensional or contour plots may be usable in monitoring the effects of ischemia and reperfusion in experimental or clinical studies. In another study (4 patients, LAD) we monitored for intra-QRS changes during PTCA. Despite signal noise and availability of recordings only from limb leads, superimposed mid-frequency components during ischemic states of the heart were observed, which disappeared when perfusion was restored. There was at least one lead that responded to changes in coronary perfusion. Figure 5.6 shows five different stages of a PTCA procedure as time plots (lead I) and CWT TFDs (topo-plots). Despite the presence of noise, the WT was able to unveil elevation of intra-QRS time-frequency components around 20 Hz during balloon inflation (ischemia), and a drop in the same components with reperfusion after balloon deflation. Frequency components 20 to 25 Hz during inflation. No substantial ST changes can be observed in the time-domain plot. The arrows show the zones of change in TFDs with ischemia and reperfusion. Note the representation of power line interference (50 Hz) as “clouds” in (b) and (d) topo plots — far from the region of interest.

Another study analyzed ECG waveforms from patients undergoing the PTCA procedure by the multiresolution wavelet method, decomposing the whole P-QRS-T intervals into coarse and detail components [26,37], as can be seen from the analysis of one pre-angioplasty ECG cycle in Figure 5.7 [26]. The PTCA procedure results in significant morphological and spectral changes within the QRS complex. It was found that certain detail components are more sensitive than others: in this study, the detail components d6 and d5 corresponding to frequency band of 2.2 to 8.3 Hz are most sensitive to ECG changes following a successful PTCA procedure. From this study it was concluded that monitoring the energy of ECG signals at different detail levels may be useful in assessing the efficacy of angioplasty procedures [37]. A benefit of

**FIGURE 5.4** Time-frequency distributions of the vector magnitude of two ECG leads during five stages of a controlled animal experiment. The frequency scale is logarithmic, 16 to 200 Hz. The z-axis represents the modulus (normalized) of the complex wavelet-transformed signal.

this approach is that a real-time monitoring instrument for the cardiac catheterization laboratory can be envisioned (whereas currently x-ray fluroscopy is needed).

*Detection of reperfusion during thrombolytic therapy.* Detecting reperfusion-related intra-QRS changes, along with ST changes, in the time–frequency domain would possibly find application in thrombolysis monitoring after myocardial infarction. At present, the ST elevation and its recovery are the main electrocardiographic indicators of acute coronary ischemia and reperfusion. Reports using continuous ST-segment monitoring have indicated that 25–50% of patients treated with intravenous thrombolytic therapy display unstable ST recovery [38], and additional reperfusion indicators are necessary. Signal averaged ECG and highest frequency ECG components (150–250 Hz) have been utilized as a reperfusion marker during thrombolysis and after angioplasty, but their utility is uncertain, since the degree of change of the energy values chosen does not appear to be satisfactory [39,40]. We have analyzed the QRS of the vector magnitude  $V =$  of body surface orthogonal ECG leads  $X, Y$  and  $Z$  during thrombolytic therapy of two patients with myocardial infarction. Figure 5.8 shows how TFDs may be affected by reperfusion during thrombolysis. Two interesting trends may be observed on this figure: (1) a mid-frequency peak present during initial ischemia (a) disappears two hours after start of thrombolytic therapy (b) due to smoother depolarization front, and (2) high-frequency components appear with reestablished perfusion, possibly due to faster propagation velocity of the depolarization front.

**5.5.1.2 Analysis of Late Potentials in the ECG**

“Late potentials” are caused by fractionation of the depolarization front after myocardial infarction [35,41]. They have been shown to be predictive of life threatening reentrant arrhythmias. Late potentials occur in the terminal portion of the QRS complex and are characterized by small amplitude and higher frequencies than in the normal QRS complex. The presence of late potentials may indicate underlying dispersion of electrical activity of the cells in the heart, and therefore may provide a substrate for production of arrhythmias. The conventional Fourier transform does not readily localize these features in time and frequency [15,42]. STFT is more useful because the concentration of signal energy at various times in the cardiac cycle is more readily identified. The STFT techniques suffer from the problem of selecting a proper window function; for example, window width can affect whether high temporal or high spectral resolution is achieved [15]. Another approach sometimes considered is the Wigner-ville distribution, which also produces a composite time–frequency distribution. However, the Wigner-ville distribution suffers from the problem of interference from cross-terms. Comparative representations by smoothed

**FIGURE 5.6** Time-domain signals (lead I) during PTCA on the LAD (upper plots) and time-frequency distributions TFD (lower plots) during (a) baseline, (b) at the end of a 3 min inflation (7 at), (c) 10 min after first inflation, reducing stenosis from 95 to 60%, (d) at the end of a 20 min inflation (6 at), (e) 10 min after first inflation, reducing stenosis from 95 to 60%. The arrows show the zones of change in TFDs with ischemia/reperfusion.

FIGURE 5.7 Detail and coarse components from one ECG cycle. The coarse components represent the low-pass filtered versions of the signal at successive scales. Detail components, d1 and d2, consist mainly of electrical interference.

FIGURE 5.8 Change of the time–frequency distributions (QRS complex) of the vector magnitude of orthogonal leads X, Y, and Z during thrombolysis (a) 5 min after start, and (b) 2 h after initiation of therapy. A mid-frequency peak has disappeared due to smoother depolarization, and high-frequency components appear due to faster propagation.

Wigner-ville, wavelet transform (scalogram), and traditional spectrogram are illustrated in Figure 5.9. This problem causes high levels of signal power to be seen at frequencies not representing the original signal; for example, signal energy contributed at certain frequencies by the QRS complex may mask the signal energy contributed by the late potentials. In this regard, wavelet analysis methods provide a more accurate picture of the localized time-scale features indicative of the late potentials [11,15,43–45]. Figure 5.10 shows that the signal energies at 60 Hz and beyond are localized in the late stage of the QRS and into the ST-segment. For comparison, the scalogram from a healthy person is illustrated in Figure 56.11. This spreading of the high frequencies into the late cycle stages of the QRS complex is a hallmark of the

late potentials. Time-scale analysis of late potentials may therefore serve as a noninvasive diagnostic tool for predicting the likelihood of life threatening arrhythmias in the heart.

### 5.5.1.3 Role of Wavelets in Arrhythmia Analysis

Detection of altered QRS morphology. Further applications to the generalized field of arrhythmia classification can be envisaged [46]. When arrhythmias, such as premature ventricular contractions (PVCs) and tachycardia do occur, the P-QRS-T complex undergoes a significant morphological change. Abnormal beats, such as PVCs, have different time-scale signatures than normal beats. Often the QRS complex may widen and sometimes invert with PVCs. As the QRS complex widens, its power spectrum shows diminished contribution at higher frequencies and these are spread out over a wider body of the signal [47,48]. This empirical description of the time-domain features of the ECG signal lends itself particularly well to analysis by time–frequency and time-scale techniques. A more challenging problem is to distinguish multiform PVCs.

Use of the orthogonal wavelet decomposition to separate dynamical activities embedded in a time series. Another interesting application of the discrete wavelet transform to arrhythmia research is the dynamical analysis of the ECG before and during ventricular tachycardia and ventricular fibrillation. Earlier works on heart rate variability have shown that heart rhythm becomes rigidly constant prior to the onset of life threatening arrhythmias, whereas the correlation dimension as a measure of randomness increases to values above 1 during disorganized rhythms like fast ventricular tachycardia, ventricular flutter, and ventricular fibrillation. This fact was used to identify patients at risk, and is promising with regard to prediction of arrhythmic episodes. Encouraging results were recently obtained by combining

**FIGURE 5.10** Healthy person (a) first recorded beat, (b) 3D representation of the modified WT for the first beat, (c) contour plot of the modified WT for the first beat, and (d) contour plot of the modified WT for the second beat.

multiresolution wavelet analysis and dynamical analysis, in an attempt to find a decorrelated scale best projecting changes in low-dimensional dynamics [49]. The authors used records 115 and 207 from the MIT Arrhythmia Database to study nonlinear dynamics preceding ventricular flutter. Distinct changes in the correlation dimension ( $D2 \approx 3$ ) in frequency band 45 to 90 Hz were observed before the onset of arrhythmia, indicating the presence of underlying low-dimensional activity.

## 5.5.2 Neurological Signal Processing

### 5.5.2.1 Evoked Potentials

Evoked potentials are the signals recorded from the brain in response to external stimulation. Evoked responses can be elicited by electrical stimulation (somatosensory evoked response), visual stimulation (visual evoked response), or auditory stimulation (brainstem auditory evoked response). Usually the signals are small, while the background noise, mostly the background EEG activity, is quite large. The low signal-to-noise ratio (SNR) necessitates use of ensemble averaging, sometimes signal averaging as many as a thousand responses [50]. After enhancing the SNR, one obtains a characteristic wave pattern that includes the stimulus artifact and an undulating pattern characterized by one or more peaks at specific latencies beyond the stimulus. Conventionally, the amplitude and the latency of the signal peaks is used in arriving at a clinical diagnosis. However, when the signals have a complex morphology, simple amplitude and latency analysis does not adequately describe all the complex changes that may occur as a result of

**FIGURE 5.11** Patient with ventricular tachycardia diagnosis (a) first beat, (b) 3D representation of the modified WT for the first beat, (c) contour plot of the modified WT for the first beat, and (d) contour plot of the modified WT for the second beat.

brain injury or disease. Time-frequency and wavelet analysis have been shown to be useful in identifying the features localized within the waveform that are most indicative of the brain's response [51].

In one recent experimental study, we evaluated the somatosensory evoked response from experimental animals in whom injury was caused by oxygen deprivation. The evoked response signal was decomposed into its coarse and detail components with the aid of the multiresolution wavelet analysis technique (Figure 5.12) [25]. The magnitude of the detail components was observed to be sensitive to the cerebral hypoxia during its early stages. Figure 5.13a,b show a time trend of the magnitude of the detail components along with the trend of the amplitude and the latency of the primary peak of the somatosensory evoked response. The experimental animal was initially challenged by nitrous gas mixture with 100% oxygen (a non-injury causing event), and later by inspired air with 7 to 8% oxygen. As expected, the amplitude trend shows an initial rise because of the 100% oxygen, and later a gradual decline in response to hypoxia. The magnitude of the detail component shows a trend more responsive to injury: while there is not a significant change in response to the non-injury causing event, the magnitude of the detail component drops quite rapidly when the brain becomes hypoxic. These data suggest that detail components of the evoked response may serve as indicators of early stages of brain injury. Evoked response monitoring can be useful in patient monitoring during surgery and in neurological critical care [52,53]. Other applications include study of cognitive or event-related potentials in human patients for normal cognitive function evaluation or for assessment of clinical situations, such as a response in Alzheimer's disease [54]. Proper characterization of evoked responses from multiple channel recordings facilitates localization of the source using the dipole localization theory [55].

FIGURE 5.14 Example of epilepsy burst.

### 5.5.2.2 EEG and Seizures

Electroencephalographic signals are usually analyzed by spectrum analysis techniques, dividing the EEG signal into various arbitrary frequency bands (a, b, q, d). Conventional spectrum analysis is useful when these events are slowly unfolding, as when a person goes to sleep, the power in the EEG shifts from higher to lower frequency bands. However, when transient events such as epileptic seizures occur, there are often sharp spikes or a bursting series of events in the recorded waveform. This form of the signal, that is temporally well localized and has a spectrum that is distinctive from normal or ongoing events, lends itself to wavelet analysis. A patient's EEG recorded over an extended period, preceding and following the seizure, was recorded and analyzed. Figure 5.14 shows a short segment of the EEG signal with a seizure burst. The multiresolution wavelet analysis technique was employed to identify the initiation of the seizure burst. Figure 5.15 shows a sudden burst onset in the magnitude of the detail components when the seizure event starts. The bursting subsides at the end of the seizure, as seen by a significant drop in the magnitude of the detail components. Wavelet analysis, thus, may be employed for the detection of onset and termination of seizures. Further possibilities exist in the use of this technique for discriminating interictal spikes and classifying them [56]. Certain seizures, like the petit mal and the grand mal epilepsy seizures, have very characteristic morphologies (e.g., spike and dome pattern). These waveforms would be expected to lend themselves very well to wavelet analysis.

### 5.5.3 Other Applications

Wavelet, or time-scale analysis is applicable to problems in which signals have characteristic morphologies or equivalently differing spectral signature attributed to different parts of the waveform, and the events of diagnostic interest are well localized in time and scale. The examples of such situations and applications are many.

FIGURE 5.15 Localization of burst example with wavelet detail components.

In cardiac signal processing, there are several potential applications. Well localized features of ECG signals, such as the P-QRS-T lend themselves well to wavelet analysis [57]. The application of wavelet analysis to ischemic-reperfusion injury changes and the late potentials has been illustrated above. This idea has been extended to the study of body surface maps recorded using numerous electrodes placed on the chest. In a preliminary study [58], spatio-temporal maps can be constructed and interpreted using time-scale analysis techniques.

In many situations noise and artifact result in inaccurate detection of the QRS complex. Wavelet analysis may prove to be helpful in removal of electrical interference from ECG [59]. Wavelet techniques have successfully been used in removing the noise from functional MRI data [8]. A more challenging application would be in distinguishing artifact from signal. Since wavelet analysis naturally decomposes the signals at different scales at well localized times, the artifactual events can be localized and eliminated. Fast computational methods may prove to be useful in real-time monitoring of ECG signal at a bedside or in analysis of signals recorded by Holter monitors.

Other cardiovascular signals, such as heart sounds may be analyzed by time-frequency or time-scale analysis techniques. Characteristic responses to various normal and abnormal conditions along with sounds that are well localized in time and scale make these signals good candidates for wavelet analysis [60]. Normal patterns may be discriminated from pathological sound patterns, or sounds from various blood vessels can be identified [61]. Blood pressure waveform similarly has a characteristic pattern amenable to time-scale analysis. The dicrotic notch of the pressure waveform results from blood flow through the valves whose opening and closing affects the pressure signal pattern. The dicrotic notch can be detected by wavelet analysis [62]. Sounds from the chest, indicative of respiratory patterns are being investigated using wavelet techniques. Applications include analysis of respiratory patterns of infants [63] and respiration during sleep [64].

Two applications in neurological signal processing, evoked response and seizure detection, are described above. Other potential applications include detection and interpretation of signals from multiple neurons obtained using microelectrodes [65]. Since waveforms (called spikes) from individual neurons (called units) have different patterns because of their separation and orientation with respect to the recording microelectrode, multiunit spike analysis becomes a challenging problem. Time-scale analysis techniques may be employed to localize and analyze the responses of individual units and from that derive the overall activity and interrelation among these units so as to understand the behavior of neural networks. An analogous problem is that of detecting and discriminating signals from “motor units,” that is, the muscle cells and fibers [66]. Signals from motor units are obtained by using small, micro or needle electrodes, and

characteristic spike trains are obtained, which can be further analyzed by time-scale analysis techniques to discriminate normal and abnormal motor unit activity.

## 5.6 Discussion and Conclusions

---

Biological signals with their time-varying nature and characteristic morphologies and spectral signatures are particularly well suited for analysis and interpretation using time-frequency and time-scale analysis techniques. For example, the P-QRS-T complex of the ECG signal shows localized low frequencies in the P- and the ST-segments and high frequencies in the QRS complex. In time-scale frame, the ischemia related changes are seen in certain detail components of the QRS complex. The late segment of the QRS cycle exhibits the so-called late potentials more easily localized by means of time-scale analysis. Other cardiovascular signals, such as pressure waves, heart sounds, and blood flow are being analyzed by the newly developed wavelet analysis algorithms. Other examples of time-scale analysis include neurological signals with potential applications in the analysis of single and multiunit recordings from neurons, evoked response, EEG, and epileptic spikes and seizures.

The desirable requirements for a successful application of time-scale analysis to biomedical signals is that events are well localized in time and exhibit morphological and spectral variations within the localized events. Objectively viewing the signal at different scales should provide meaningful new information. For example, are there fine features of signal that are observable only at scales that pick out the detail components? Are there features of the signal that span a significant portion of the waveform so that they are best studied at a coarse scale. The signal analysis should be able to optimize the trade-off between time and scale, that is, distinguish short lasting events and long lasting events.

For these reasons, the signals described in this article have been found to be particularly useful models for data analysis. However, one needs to be cautious in using any newly developed tool or technology. Most important questions to be addressed before proceeding with a new application are: Is the signal well suited to the tool, and in applying the tool, are any errors inadvertently introduced? Does the analysis provide a new and more useful interpretation of the data and assist in the discovery of new diagnostic information?

Wavelet analysis techniques appear to have robust theoretical properties allowing novel interpretation of biomedical data. As new algorithms emerge, they are likely to find application in the analysis of more diverse biomedical signals. Analogously, the problems faced in the biomedical signal acquisition and processing world will hopefully stimulate development of new algorithms.

### 6.1 Introduction

---

The past 20 years witnessed an expansion of power spectrum estimation techniques, which have proved essential in many applications, such as communications, sonar, radar, speech/image processing, geophysics, and biomedical signal processing [1–3]. In power spectrum estimation, the process under consideration is treated as a superposition of statistically uncorrelated harmonic components. The distribution of power among these frequency components is the power spectrum. As such phase relations between frequency components are suppressed. The information in the power spectrum is essentially present in the autocorrelation sequence, which would suffice for the complete statistical description of a Gaussian process of known mean. However, there are applications where one would need to obtain information regarding deviations from the Gaussianity assumption and presence of nonlinearities. In these cases power spectrum is of little help, and a look beyond the power spectrum or autocorrelation domain is needed. Higher-order spectra (HOS) (of order greater than two), which are defined in terms of higher-order cumulants of the data, do contain such information [4]. The third order spectrum is commonly referred to as bispectrum and the fourth-order as trispectrum. The power spectrum is also a member of the higher-order spectral class; it is the second-order spectrum.

The HOS consist of higher-order moment spectra, which are defined for deterministic signals, and cumulant spectra, which are defined for random processes. In general there are three motivations behind the use of HOS in signal processing (1) to suppress Gaussian noise of unknown mean and variance, (2) to reconstruct the phase as well as the magnitude response of signals or systems, and (3) to detect and characterize nonlinearities in the data.

The first motivation stems from the property of Gaussian processes to have zero higher-order spectra of order greater than two. Due to this property, HOS are high signal-to-noise ratio domains in which one can perform detection, parameter estimation, or even signal reconstruction even if the time domain noise is spatially correlated. The same property of cumulant spectra can provide a means of detecting and characterizing deviations of the data from the Gaussian model.

The second motivation is based on the ability of cumulant spectra to preserve the Fourier phase of signals. In the modeling of time series, second-order statistics (autocorrelation) have been heavily used because they are the result of least-squares optimization criteria. However, an accurate phase reconstruction in the autocorrelation domain can be achieved only if the signal is at minimum phase. Nonminimum phase signal reconstruction can be achieved only in the HOS domain, due to the HOS ability to preserve the phase.

Being nonlinear functions of the data, HOS are quite natural tools in the analysis of nonlinear systems operating under a random input. General relations for stationary random data passing through an arbitrary linear system exist and have been studied extensively. Such expressions, however, are not available for nonlinear systems, where each type of nonlinearity must be studied separately. Higher-order correlations between input and output can detect and characterize certain nonlinearities [5], and for this purpose several higher-order spectra based methods have been developed.

This chapter is organized as follows. In Section 6.2 definitions and properties of cumulants and higher-order spectra are introduced. In Section 6.3 methods for estimation of HOS from finite length data are presented and the asymptotic statistics of the corresponding estimates are provided. In Section 6.4 methods for identification of a linear time-invariant system from HOS of the system output are outlined, while in Section 6.6, nonlinear system estimation is considered. Section 6.6 summarizes the research activity related to HOS as applied to biomedical signal analysis and provides details on a particular application, namely the improvement of resolution of medical ultrasound images via HOS is discussed.

## 6.2 Definitions and Properties of HOS

In this chapter only random one-dimensional processes are considered. The definitions can be easily extended to the two-dimensional case [6].

The joint moments of order  $r$  of the random variables  $x_1, \dots, x_n$  are given by [7]:

$$\begin{aligned} \text{Mom}[x_1^{k_1}, \dots, x_n^{k_n}] &= E\{x_1^{k_1}, \dots, x_n^{k_n}\} \\ &= (-j)^r \frac{\partial^r \Phi(\omega_1, \dots, \omega_n)}{\partial \omega_1^{k_1} \dots \partial \omega_n^{k_n}} \Bigg|_{\omega_1 = \dots = \omega_n = 0} \end{aligned} \quad (6.1)$$

where  $k_1 + \dots + k_n = r$ , and  $\Phi(\cdot)$  is their joint characteristic function. The corresponding joint cumulants are defined as:

$$\text{Cum}[x_1^{k_1}, \dots, x_n^{k_n}] = (-j)^r \frac{\partial^r \ln \Phi(\omega_1, \dots, \omega_n)}{\partial \omega_1^{k_1} \dots \partial \omega_n^{k_n}} \Bigg|_{\omega_1 = \dots = \omega_n = 0} \quad (6.2)$$

For a stationary discrete time random process  $x(k)$  ( $k$  denotes discrete time), the *moments* of order  $n$  are given by:

$$m_n^x(\tau_1, \tau_2, \dots, \tau_{n-1}) = E\{x(k)x(k + \tau_1) \cdots x(k + \tau_{n-1})\} \quad (6.3)$$

where  $E\{\cdot\}$  denotes expectation. The  $n$ th order cumulants are functions of the moments of order up to  $n$ , that is,

First-order cumulants:

$$c_1^x = m_1^x = E\{x(k)\} \quad (\text{mean}) \quad (6.4)$$

Second-order cumulants:

$$c_2^x(\tau_1) = m_2^x(\tau_1) - (m_1^x)^2 \quad (\text{covariance}) \quad (6.5)$$

Third-order cumulants:

$$c_3^x(\tau_1, \tau_2) = m_3^x(\tau_1, \tau_2) - (m_1^x)[m_2^x(\tau_1) + m_2^x(\tau_2) + m_2^x(\tau_2 - \tau_1)]2(m_1^x)^3 \quad (6.6)$$

Fourth-order cumulants:

$$\begin{aligned} c_4^x(\tau_1, \tau_2, \tau_3) = & m_4^x(\tau_1, \tau_2, \tau_3) - m_2^x(\tau_1)m_2^x(\tau_3 - \tau_2) - m_2^x(\tau_2)m_2^x(\tau_3 - \tau_1) - m_2^x(\tau_3)m_2^x(\tau_2 - \tau_1) \\ & - m_1^x[m_3^x(\tau_2 - \tau_1, \tau_3 - \tau_1) + m_3^x(\tau_2, \tau_3) + m_3^x(\tau_2, \tau_4) + m_3^x(\tau_1, \tau_2)] \\ & + (m_1^x)^2[m_2^x(\tau_1) + m_2^x(\tau_2) + m_2^x(\tau_3) + m_2^x(\tau_3 - \tau_1) + m_2^x(\tau_3 - \tau_2) \\ & + m_1^x(\tau_2 - \tau_1)] - 6(m_1^x)^4 \end{aligned} \quad (6.7)$$

The general relationship between cumulants and moments can be found in Reference 4.

Some important properties of moments and cumulants are summarized next.

[P1] If  $x(k)$  is a jointly Gaussian process, then  $c_n^x(\tau_1, \tau_2, \dots, \tau_{n-1}) = 0$  for  $n > 2$ . In other words, all the information about a Gaussian process is contained in its first- and second-order cumulants. This property can be used to suppress Gaussian noise, or as a measure for non-Gaussianity in time series.

[P2] If  $x(k)$  is symmetrically distributed, then  $c_3^x(\tau_1, \tau_2) = 0$ . Third-order cumulants suppress not only Gaussian processes, but also all symmetrically distributed processes, such as uniform, Laplace, and Bernoulli–Gaussian.

[P3] Additivity holds for cumulants. If  $x(k) = s(k) + w(k)$ , where  $s(k)$ ,  $w(k)$  are stationary and statistically independent random processes, then  $c_n^x(\tau_1, \tau_2, \dots, \tau_{n-1}) = c_n^s(\tau_1, \tau_2, \dots, \tau_{n-1}) + c_n^w(\tau_1, \tau_2, \dots, \tau_{n-1})$ . It is important to note that additivity does not hold for moments.

If  $w(k)$  is a Gaussian representing noise which corrupts the signal of interest,  $s(k)$ , then by means of (P2) and (P3), we conclude that  $c_n^x(\tau_1, \tau_2, \dots, \tau_{n-1}) = c_n^s(\tau_1, \tau_2, \dots, \tau_{n-1})$ , for  $n > 2$ . In other words, in higher-order cumulant domains the signal of interest propagates noise free. Property (P3) can also provide a measure of the statistical dependence of two processes.

[P4] if  $x(k)$  has zero mean, then  $c_n^x(\tau_1, \dots, \tau_{n-1}) = m_n^x(\tau_1, \dots, \tau_{n-1})$ , for  $n \leq 3$ .

Higher-order spectra are defined in terms of either cumulants (e.g., cumulant spectra) or moments (e.g., moment spectra).

Assuming that the  $n$ th-order cumulant sequence is absolutely summable, the  $n$ th-order cumulant spectrum of  $x(k)$ ,  $C_n^x(\omega_1, \omega_2, \dots, \omega_{n-1})$ , exists, and is defined to be the  $(n - 1)$ -dimensional Fourier transform of the  $n$ th-order cumulant sequence. In general,  $C_n^x(\omega_1, \omega_2, \dots, \omega_{n-1})$  is complex, that is, it has magnitude and phase. In an analogous manner, moment spectrum is the multidimensional Fourier transform of the moment sequence.

If  $v(k)$  is a stationary non-Gaussian process with zero mean and  $n$ th-order cumulant sequence

$$c_n^v(\tau_1, \dots, \tau_{n-1}) = \gamma_n^v \delta(\tau_1, \dots, \tau_{n-1}) \quad (6.8)$$

where  $\delta(\cdot)$  is the delta function,  $\nu(k)$  is said to be  $n$ th order white. Its  $n$ th order cumulant spectrum is then flat and equal to  $\gamma_n^x$ .

Cumulant spectra are more useful in processing random signals than moment spectra since they possess properties that the moment spectra do not share, that is, properties P1, P3, and flatness of spectra corresponding to higher-order white noise.

## 6.3 HOS Computation from Real Data

The definitions of cumulants presented in the previous section are based on expectation operations, and they assume infinite length data. In practice we always deal with data of finite length, therefore, the cumulants can only be estimated. Two methods for cumulants and spectra estimation are presented next for the third-order case.

### 6.3.1 Indirect Method

Let  $x(k)$ ,  $k = 0, \dots, N - 1$  be the available data.

1. Segment the data into  $K$  records of  $M$  samples each. Let  $x^i(k)$ ,  $k = 0, \dots, M - 1$ , represent the  $i$ th record.
2. Subtract the mean of each record.
3. Estimate the moments of each segment  $x^i(k)$  as follows:

$$l_1 = \max(0, -\tau_1, -\tau_2), l_2 = \min(M - 1 - \tau_1, M - 1 - \tau_2, M - 1), \quad |\tau_1| < L, \quad |\tau_2| < L, \\ i = 1, 2, \dots, K. \quad (6.9)$$

Since each segment has zero mean, its third-order moments and cumulants are identical, that is,  $c_3^{x_i}(\tau_1, \tau_2) = m_3^{x_i}(\tau_1, \tau_2)$ .

4. Compute the average cumulants as:

$$\hat{c}_3^x(\tau_1, \tau_2) = \frac{1}{K} \sum_{i=1}^K m_3^{x_i}(\tau_1, \tau_2) \quad (6.10)$$

5. Obtain the third-order spectrum (bispectrum) estimate as the two-dimensional Discrete Fourier Transform of size  $M \times M$  of the windowed  $\hat{c}_3^{x_i}(\tau_1, \tau_2)$ , that is,

$$\hat{C}_3^x(k_1, k_2) = \sum_{\tau_1=-L}^L \sum_{\tau_2=-L}^L \hat{c}_3^x(\tau_1, \tau_2) e^{-j((2\pi/M)k_1\tau_1 + (2\pi/M)k_2\tau_2)} w(\tau_1, \tau_1), \quad k_1, k_2 = 0, \dots, M - 1 \quad (6.11)$$

where  $L < M - 1$ , and  $w(\tau_1, \tau_2)$  is a two-dimensional window of bounded support, introduced to smooth out edge effects. The bandwidth of the final bispectrum estimate is  $\Delta = 1/L$ .

A complete description of appropriate windows that can be used in Equation 6.11 and their properties can be found in Reference 4. A good choice of cumulant window is:

$$w(\tau_1, \tau_2) = d(\tau_1)d(\tau_2)d(\tau_1 - \tau_2) \quad (6.12)$$

where

$$d(\tau) = \begin{cases} \frac{1}{\pi} \left| \sin \frac{\pi \tau}{L} \right| + \left( 1 - \frac{|\tau|}{L} \right) \cos \frac{\pi \tau}{L} & |\tau| \leq L \\ 0 & |\tau| > L \end{cases} \quad (6.13)$$

which is known as the minimum bispectrum bias supremum [8].

### 6.3.2 Direct Method

Let  $x(k)$ ,  $k = 1, \dots, N$  be the available data.

1. Segment the data into  $K$  records of  $M$  samples each. Let  $x^i(k)$ ,  $k = 0, \dots, M-1$ , represent the  $i$ th record.
2. Subtract the mean of each record.
3. Compute the Discrete Fourier Transform  $X^i(k)$  of each segment, based on  $M$  points, that is,

$$X^i(k) = \sum_{n=0}^{M-1} x^i(n) e^{-j(2\pi/M)nk}, \quad k = 0, 1, \dots, M-1, \quad i = 1, 2, \dots, K \quad (6.14)$$

4. The third-order spectrum of each segment is obtained as

$$C_3^{x_i}(k_1, k_2) = \frac{1}{M} X^i(k_1) X^i(k_2) X^{i*}(k_1 + k_2), \quad i = 1, \dots, K \quad (6.15)$$

Due to the bispectrum symmetry properties,  $C_3^{x_i}(k_1, k_2)$  needs to be computed only in the triangular region  $0 \leq k_2 \leq k_1, k_1 + k_2 < M/2$ .

5. In order to reduce the variance of the estimate, additional smoothing over a rectangular window of size  $(M_3 \times M_3)$  can be performed around each frequency, assuming that the third-order spectrum is smooth enough, that is,

$$\hat{C}_3^{x_i}(k_1, k_2) = \frac{1}{M_3^2} \sum_{n_1=-M_3/2}^{M_3/2-1} \sum_{n_2=-M_3/2}^{M_3/2-1} C_3^{x_i}(k_1 + n_1, k_2 + n_2) \quad (6.16)$$

6. Finally, the third-order spectrum is given as the average over all third-order spectra, that is,

$$\hat{C}_3^x(k_1, k_2) = \frac{1}{K} \sum_{i=1}^K \hat{C}_3^{x_i}(k_1, k_2) \quad (6.17)$$

The final bandwidth of this bispectrum estimate is  $\Delta = M_3/M$ , which is the spacing between frequency samples in the bispectrum domain.

For large  $N$ , and as long as

$$\Delta \rightarrow 0 \quad \text{and} \quad \Delta^2 N \rightarrow \infty \quad (6.18)$$

both the direct and the indirect methods produce asymptotically unbiased and consistent bispectrum estimates, with real and imaginary part variances [9]:

$$\begin{aligned} \text{var}(\text{Re}[\hat{C}_3^x(k_1, k_2)]) &= \text{var}(\text{Im}[\hat{C}_3^x(k_1, k_2)]) \\ &= \frac{1}{\Delta^2 N} C_2^x(k_1) C_2^x(k_2) C_2^x(k_1 + k_2) = \begin{cases} \frac{VL^2}{MK} C_2^x(k_1) C_2^x(k_2) C_2^x(k_1 + k_2) & \text{indirect} \\ \frac{M}{KM_3^2} C_2^x(k_1) C_2^x(k_2) C_2^x(k_1 + k_2) & \text{direct} \end{cases} \end{aligned} \quad (6.19)$$

where  $V$  is the energy of the bispectrum window.

From the above expressions, it becomes apparent that the bispectrum estimate variance can be reduced by increasing the number of records, or reducing the size of the region of support of the window in the cumulant domain ( $L$ ), or increasing the size of the frequency smoothing window ( $M_3$ ), etc. The relation between the parameters  $M, K, L, M_3$  should be such that 6.18 is satisfied.

## 6.4 Linear Processes

Let  $x(k)$  be generated by exiting a linear, time-invariant (LTI), exponentially stable, mixed-phase system with frequency response  $H(\omega)$  (or impulse response  $h(k)$ ), with an  $n$ th order white, zero-mean, non-Gaussian stationary process  $v(k)$ , that is,

$$x(k) = v(k) * h(k) \quad (6.20)$$

where  $*$  denotes convolution.

The output  $n$ th-order cumulant equals [10]:

$$c_n^x(\tau_1, \dots, \tau_{n-1}) = \gamma_n^v \sum_{k=0}^{\infty} h(k) h(k + \tau_1) \cdots h(k + \tau_{n-1}), \quad n \geq 3 \quad (6.21)$$

where  $\gamma_n^v$  is a scalar constant and equals the  $n$ th-order spectrum of  $v(k)$ . The output  $n$ th-order cumulant spectrum is given by

$$C_n^x(\omega_1, \omega_2, \dots, \omega_{n-1}) = \gamma_n^v H(\omega_1) \cdots H(\omega_{n-1}) H^*(\omega_1 + \cdots + \omega_{n-1}) \quad (6.22)$$

For a linear non-Gaussian random process  $x(k)$ , the  $n$ th-order spectrum can be factorized as in Equation 6.22 for every order  $n$ , while for a nonlinear process such a factorization might be valid for some orders only (it is always valid for  $n = 2$ ).

It can be easily shown that the cumulant spectra of successive orders are related as follows:

$$C_n^x(\omega_1, \omega_2, \dots, 0) = C_{n-1}^x(\omega_1, \omega_2, \dots, \omega_{n-2}) H(0) \frac{\gamma_n^v}{\gamma_{n-1}^v} \quad (6.23)$$

For example, the power spectrum of a non-Gaussian linear process can be reconstructed from the bispectrum up to a scalar factor, that is,

$$C_3^x(\omega, 0) = C_2^x(\omega) \frac{\gamma_3^v}{\gamma_2^v} \quad (6.24)$$

While for  $n = 2$ , Equation 6.22 provides the magnitude only of  $H(\omega)$ , as a function of  $C_n^x(\omega_1, \omega_2, \dots, \omega_{n-1})$ , for  $n > 2$  both the magnitude and phase of  $H(\omega)$  can be obtained. A significant amount of research has been devoted to estimating the system phase from the phase of the bispectrum or trispectrum [4,11–13].

Let

$$y(k) = x(k) + w(k) \quad (6.25)$$

where  $x(k)$  was defined in Equation 6.20, and  $w(k)$  is zero-mean Gaussian noise, uncorrelated to  $x(k)$ . Methods for reconstructing  $h(k)$  from  $y(k)$  can be divided into two main categories: nonparametric and parametric.

### 6.4.1 Nonparametric Methods

Nonparametric methods reconstruct the system by recovering its Fourier phase and magnitude. Some utilize the whole bispectrum (or polyspectrum) information [11,14–18], and others use fixed, one-dimensional polyspectrum slices [19,20]. In References 12 and 21, methods for system recovery from arbitrarily selected HOS slices have been proposed. A system method based on preselected polyspectrum slices, allows regions where polyspectrum estimates exhibit high variance, or regions where the ideal polyspectrum is expected to be zero, such as in the case of bandlimited systems to be avoided. Assuming that there existed a mechanism to select “good” slices, it can also lead to computational savings.

Let the bispectrum of  $y(k)$  in Equation 6.25, that is,  $C_3^x(\omega_1, \omega_2)$ , be discretized on a square grid of size  $2\pi/N \times 2\pi/N$ , and let  $\{C_3^y(m, l), m = 0, \dots, N-1\}$ ,  $\{C_3^y(m, l+r), m = 0, \dots, N-1\}$  be two bispectral slices. In Reference 21 it was shown that unique identification of the system impulse response can be performed base on two horizontal slices of the discretized third-order spectrum of the system output, as long as the distance between slices, that is,  $r$  and  $N$  are co-prime numbers. Let

$$\hat{\mathbf{h}} = [\log H(1), \dots, \log H(N-1)]^T ((N-1) \times 1) \quad (6.26)$$

where  $H(k)$  is the Discrete Fourier Transform of  $h(n)$ . Then  $\hat{\mathbf{h}}$  can be obtained as the solution of the system:

$$\mathbf{A}\hat{\mathbf{h}} = \mathbf{b} \quad (6.27)$$

where

$$\begin{aligned} b(k) &= \log C_3^h(-k-r-l, l) - \log C_3^h(-k-r-l, l+r) + c_{l,r} \\ k &= 0, \dots, N-1 \\ c_{l,r} &= \frac{1}{N} \sum_{k=0}^{N-1} [\log C_3^y(k, l+r) - \log C_3^y(k, l)] \end{aligned} \quad (6.28)$$

and  $A$  is a  $[(N-1) \times (N-1)]$  sparse matrix; its first row contains a 1 at the  $r$ th column and 0s elsewhere. The  $k$ th row contains a  $-1$  at column  $(k-1) \bmod N$ , and a 1 at column  $(k+r-1) \bmod N$ . Although  $b(k)$  requires the computation of the logarithm of a complex quantity, it was shown in Reference 21, that the log-bispectrum can be computed based on the principal argument of the bispectral phase, thus bypassing the need for two-dimensional phase unwrapping. The bispectrum needed in this method can be substituted with a bispectral estimate, obtained with any of the methods outlined in Chapter 6.3. Reduction of the HOS estimate variance can be achieved via a low-rank approach [22–24].

The above described reconstruction method can be easily extended to any order spectrum [21]. Matlab code for this method can be found at <http://www.ece.drexel.edu/CSPL>.

### 6.4.2 Parametric Methods

These methods fit a parametric model to the data  $x(k)$ . For example, let us fit a real autoregressive moving average (ARMA) model to  $x(k)$ , that is,

$$\sum_{i=0}^p a(i)x(k-i) = \sum_{j=0}^q b(j)v(k-j) \quad (6.29)$$

where  $v(k)$  is a stationary zero-mean  $n$ th order white non-Gaussian process, and  $a(i)$  and  $b(j)$  represent the AR and MA parameters. Let  $y(k)$  be as defined in Equation 6.25. For estimation of the AR parameters from  $y(k)$ , equations analogous to the Yule-Walker equations can be derived based on third-order cumulants of  $y(k)$ , that is,

$$\sum_{i=0}^p a(i)c_3^y(\tau-i, j) = 0, \quad \tau > q \quad (6.30)$$

or

$$\sum_{i=1}^p a(i)c_3^y(\tau-i, j) = -c_3^y(\tau, j), \quad \tau > q \quad (6.31)$$

where it was assumed  $a(0) = 1$ . Concatenating Equation 6.31 for  $\tau = q+1, \dots, q+M, M \geq 0$ , and  $j = q-p, \dots, q$ , the matrix equation

$$Ca = c \quad (6.32)$$

can be formed, where  $C$  and  $c$  are a matrix and a vector, respectively, formed by third-order cumulants of the process according to Equation 6.31, and the vector  $a$  contains the AR parameters. If the AR order  $p$  is unknown and Equation 6.32 is formed based on an overestimate of  $p$ , the resulting matrix  $C$  always has rank  $p$ . In this case the AR parameters can be obtained using a low-rank approximation of  $C$  [25].

Using the estimated AR parameters,  $\hat{a}(i)$ ,  $i = 1, \dots, p$ , a  $p$ th order filter with transfer function  $\hat{A}(z) = 1 + \sum_{i=1}^p \hat{a}(i)z^{-i}$  can be constructed. Based on the filtered-through  $\hat{A}(z)$  process  $y(k)$ , that is,  $\tilde{y}(k)$ , or otherwise known as the residual time series [25], the MA parameters can be estimated via any MA method [6], for example:

$$b(k) = \frac{\tilde{c}_3^y(q, k)}{\tilde{c}_3^y(q, 0)}, \quad k = 0, 1, \dots, q \quad (6.33)$$

known as the  $c(q, k)$  formula [26].

Practical problems associated with the described approach are sensitivity to model order mismatch, and AR estimation errors that propagate in the estimation of the MA parameters. Additional parametric methods can be found in References 4, 6, and 27–31.

## 6.5 Nonlinear Processes

Despite the fact that progress has been established in developing the theoretical properties of nonlinear models, only a few statistical methods exist for detection and characterization of nonlinearities from a finite set of observations. In this chapter we will consider nonlinear Volterra systems excited by Gaussian

FIGURE 6.1 Second-order Volterra system. Linear and quadratic parts are connected in parallel.

stationary inputs. Let  $y(k)$  be the response of a discrete time invariant,  $p$ th order, Volterra filter whose input is  $x(k)$ . Then,

$$y(k) = h_0 + \sum_i \sum_{\tau_1, \dots, \tau_i} h_i(\tau_1, \dots, \tau_i) x(k - \tau_1) \cdots x(k - \tau_i) \tag{6.34}$$

where  $h_i(\tau_1, \dots, \tau_i)$  are the Volterra kernels of the system, which are symmetric functions of their arguments; for causal systems  $h_i(\tau_1, \dots, \tau_i) = 0$  for any  $\tau_i < 0$ .

The output of a second-order Volterra system when the input is zero-mean stationary is

$$y(k) = h_0 + \sum_{\tau_1} h_1(\tau_1) x(k - \tau_1) + \sum_{\tau_1} \sum_{\tau_2} h_2(\tau_1, \tau_2) x(k - \tau_1) x(k - \tau_2) \tag{6.35}$$

Equation 6.35 can be viewed as a parallel connection of a linear system  $h_1(\tau_1)$  and a quadratic system  $h_2(\tau_1, \tau_2)$  as illustrated in Figure 6.1. Let

$$c_2^{xy}(\tau) = E\{x(k + \tau)[y(k) - m_1^y]\} \tag{6.36}$$

be the cross-covariance of input and output, and

$$c_2^{xxy}(\tau_1, \tau_2) = E\{x(k + \tau_1)x(k + \tau_2)[y(k) - m_1^y]\} \tag{6.37}$$

be the third-order cross-cumulant sequence of input and output.

The system's linear part can be obtained by [32]

$$H_1(-\omega) = \frac{C_2^{xy}(\omega)}{C_2^x(\omega)} \tag{6.38}$$

and the quadratic part by

$$H_2(-\omega_1, -\omega_2) = \frac{C_3^{xxy}(\omega_1, \omega_2)}{2C_2^x(\omega_1)C_2^x(\omega_2)} \tag{6.39}$$

where  $C_2^{xy}(\omega)$  and  $C_3^{xxy}(\omega_1, \omega_2)$  are the Fourier transforms of  $c_2^{xy}(t)$  and  $c_2^{xxy}(\tau_1, \tau_2)$ , respectively. It should be noted that the above equations are valid only for Gaussian input signals. More general results assuming non-Gaussian input have been obtained in References 33 and 34. Additional results on particular nonlinear systems have been reported in References 35 and 36.

An interesting phenomenon, caused by a second-order nonlinearity, is the quadratic-phase coupling. There are situations where nonlinear interaction between two harmonic components of a process

contribute to the power of the sum and/or difference frequencies. The signal

$$x(k) = A \cos(\lambda_1 k + \theta_1) + B \cos(\lambda_2 k + \theta_2) \tag{6.40}$$

after passing through the quadratic system:

$$z(k) = x(k) + \epsilon x^2(k), \quad \epsilon \neq 0 \tag{6.41}$$

contains cosinusoidal terms in  $(\lambda_1, \theta_1), (\lambda_2, \theta_2), (2\lambda_1, 2\theta_1), (2\lambda_2, 2\theta_2), (\lambda_1 + \lambda_2, \theta_1 + \theta_2), (\lambda_1 - \lambda_2, \theta_1 - \theta_2)$ . Such a phenomenon that results in phase relations that are the same as the frequency relations is called quadratic phase coupling [37]. Quadratic phase coupling can arise only among harmonically related components. Three frequencies are harmonically related when one of them is the sum or difference of the other two. Sometimes it is important to find out if peaks at harmonically related positions in the power spectrum are in fact phase coupled. Due to phase suppression, the power spectrum is unable to provide an answer to this problem. As an example, consider the process [38]

$$x(k) = \sum_{i=1}^6 \cos(\lambda_i k + \phi_i) \tag{6.42}$$

where  $\lambda_1 > \lambda_2 > 0, \lambda_4 + \lambda_5 > 0, \lambda_3 = \lambda_1 + \lambda_2, \lambda_6 = \lambda_4 + \lambda_5, \phi_1, \dots, \phi_5$  are all independent, uniformly distributed random variables over  $(0, 2\pi)$ , and  $\phi_6 = \phi_4 + \phi_5$ . Among the six frequencies  $(\lambda_1, \lambda_2, \lambda_3)$  and  $(\lambda_4, \lambda_5, \lambda_6)$  are harmonically related, however, only  $\lambda_6$  is the result of phase coupling between  $\lambda_4$  and  $\lambda_5$ . The power spectrum of this process consists of six impulses at  $\lambda_i, i, \dots, 6$  (Figure 6.2), offering no indication whether each frequency component is independent or a result of frequency coupling. On the other hand, the bispectrum of  $x(k)$  (evaluated in its principal region) is zero everywhere, except at point

**FIGURE 6.2** Quadratic phase coupling. (a) The power spectrum of the process described in Equation 6.42 cannot determine what frequencies are coupled. (b) The corresponding magnitude bispectrum is zero everywhere in the principle region, except at points corresponding to phase coupled frequencies.

$(\lambda_4, \lambda_5)$  of the  $(\omega_1, \omega_2)$  plane, where it exhibits an impulse (Figure 6.2b). The peak indicates that only  $\lambda_4, \lambda_5$  are phase coupled.

The bicoherence index, defined as

$$P_3^x(\omega_1, \omega_2) = \frac{C_3^x(\omega_1, \omega_2)}{\sqrt{C_2^x(\omega_1)C_2^x(\omega_2)C_2^x(\omega_1 + \omega_2)}} \quad (6.43)$$

has been extensively used in practical situations for the detection and quantification of quadratic phase coupling [37]. The value of the bicoherence index at each frequency pair indicates the degree of coupling among the frequencies of that pair. Almost all bispectral estimators can be used in Equation 6.43. However, estimates obtained based on parametric modeling of the bispectrum have been shown to yield resolution superior [38,39] to the ones obtained with conventional methods.

## 6.6 HOS in Biomedical Signal Processing

The applications of HOS on biomedical signals are clustered according to the HOS property they most rely on, that is, (1) the ability to describe non-Gaussian processes and preserve phase, (2) the Gaussian noise immunity, and (3) the ability to characterize nonlinearities.

In the first class are the works of References 40 to 42, where ultrasound imaging distortions are estimated from the ultrasound echo and subsequently compensated for, to improve the diagnostic quality of the image. HOS have been used in modeling the ultrasound radio-frequency (RF) echo [46], where schemes for estimation of resolvable periodicity as well as correlations among nonresolvable scatters have been proposed. The “tissue color,” a quantity that describes the scatterer spatial correlations, and which can be obtained from the HOS of the RF echo, has been proposed [43] as a tissue characterization feature. The skewness and kurtosis of mammogram images have been proposed in Reference 44 as a tool for detecting microcalcifications in mammograms.

In the second class are methods that process multicomponent biomedical signals, treating one component as the signal of interest and the rest as noise. HOS have been used in Reference 45 to process lung sounds in order to suppress sound originating from the heart, and in Reference 46 to detect human afferent nerve signals, which are usually observed in very poor signal-to-noise ratio conditions.

Most of the HOS applications in the biomedical area belong to the third class, and usually investigate the formation and the nature of frequencies present in signals through the presence of quadratic phase coupling (QPC). The bispectrum has been applied in EEG signals of the rat during various vigilance states [47], where QPC between specific frequencies was observed. QPC changes in auditory evoked potentials of healthy subjects and subjects with Alzheimer’s dementia has been reported [48]. Visual evoked potentials have been analyzed via the bispectrum in References 49 to 51. Bispectral analysis of interactions between electrocerebral activity resulting from stimulation of the left and right visual fields revealed nonlinear interactions between visual fields [52]. The bispectrum has been used in the analysis of electromyogram recruitment [53], and in defining the pattern of summation of muscle fiber twitches in the surface mechanomyogram generation [54]. QPC was also observed in the EEG of humans [55,56].

In the sequel, presented in some detail are the application of HOS on improving the resolution of ultrasound images, a topic that has recently attracted a lot of attention.

Ultrasonic imaging is a valuable tool in the diagnosis of tumors of soft tissues. Some of the distinctive features of ultrasound are its safe, nonionizing acoustic radiation, and its wide availability as a low cost, portable equipment. The major drawback that limits the use of ultrasound images in certain cases (e.g., breast imaging) is poor resolution. In B-Scan images, the resolution is compromised due to: (1) the finite bandwidth of the ultrasonic transducer, (2) the non-negligible beam width, and (3) phase aberrations and velocity variations arising from acoustic inhomogeneity of tissues themselves. The observed ultrasound image can be considered as a distorted version of the true tissue information. Along the axial

direction the distortion is dominated by the pulse-echo wavelet of the imaging system, while along the lateral direction the distortion is mainly due to finite-width lateral beam profile. Provided that these distortions are known in advance, or non-invasively measurable, their effects can be compensated for in the observed image. With propagation in tissue, however, both axial and lateral distortions change due to the inhomogeneities of the media and the geometry of the imaging system. They also change among different tissue types and individuals. Distortions measure in a simplified setting, for example, in a water tank, are rarely applicable to clinical images, due to the effects of tissue-dependent components. Therefore, distortions must be estimated based on the backscattered RF data that lead to the B-mode image.

Assuming a narrow ultrasound beam, linear propagation and weak scattering, the ultrasonic RF echo,  $y_i(n)$ , corresponding to the  $i$ th axial line in the B-mode image is modeled as [40]:

$$y_i(n) = h_i(n) * f_i(n) + w_i(n), \quad i = 1, 2, \dots \quad (6.44)$$

where  $n$  is the discrete time;  $w_i(n)$  is observation noise;  $f_i(n)$  represents the underlying tissue structure and is referred to as tissue response; and  $h_i(n)$  represents the axial distortion kernel. Let us assume that: (A1)  $y_i(n)$  is non-Gaussian; (A2)  $f_i(n)$  is white, non-Gaussian random process; (A3)  $w_i(n)$  is Gaussian noise uncorrelated with  $f_i(n)$ ; and (A4)  $y_i(n)$  is a short enough segment, so that the attenuation effects stay constant over its duration. (Long segments of data can be analyzed by breaking them into a sequence of short segments.) A similar model can be assumed to hold in the lateral direction of the RF image.

Even though the distortion kernels were known to be non-minimum phase [57], their estimation was mostly carried out using second-order statistics (SOS), such as autocorrelation or power spectrum, thereby neglecting Fourier phase information. Phase is important in preserving edges and boundaries in images. It is particularly important in medical ultrasound images where the nature of edges of a tumor provide important diagnostic information about the malignancy. Complex cepstrum-based operations that take phase information into account have been used [42] to estimate distortions. HOS retain phase and in addition, are not as sensitive to singularities as the cepstrum. HOS were used [40] for the first time to estimate imaging distortions from B-scan images. It was demonstrated that the HOS-based distortion estimation and subsequent image deconvolution significantly improved resolution. For the case of breast data, it was demonstrated [41] that deconvolution via SOS-based distortion estimates was not as good as its HOS counterpart.

In the following we present some results of distortion estimation followed by deconvolution of clinical B-scan images of human breast data. The data were obtained using a flat linear array transducer with a nominal center frequency of 7.5 MHz on a clinical imaging system UltraMark-9 Advanced Technology Laboratories. Data were sampled at a rate of 20 MHz. Figure 6.3a shows parts of the original image, where the the logarithm of the envelope has been used for display purposes. Axial and lateral distortion kernels were estimated from the RF data via the HOS-based non-parametric method outlined in Section 6.4 of this chapter [21], and also via an SOS power cepstrum based method [41]. Each kernel estimate was obtained from a rectangular block of RF data described by  $(x, y, N_x, N_y)$ , where  $(x, y)$  are the coordinates of the upper left corner of the block,  $N_x$  is its lateral width, and  $N_y$  is the axial height. Note that  $y$  corresponds to the depth of the upper left corner of the image block from the surface of the transducer. In the following, all dimensions are specified in sample numbers. The size of the images used was  $192 \times 1024$ . Assuming that within the same block the axial distortion kernel does not significantly depend on the lateral location of the RF data, all axial RF data in the block can be concatenated to form a longer one-dimensional vector. In both HOS and SOS based axial kernel estimations, it was assumed that  $N_x = 10$ ,  $N_y = 128$ ,  $N = 128$ . Note that the  $N_y = 128$  samples correspond to 5 mm in actual tissue space, as is reasonable to assume that attenuation over such a small distance may be assumed constant. Fifty kernels were estimated from the blocks  $(x, 400, 10, 128)$ , the  $x$  taking values in the range  $1, \dots, 50$ . Lateral kernels were estimated from the same images with parameters  $N_x = 192$ ,  $N_y = 10$ , and  $N = 64$ . All the kernels were estimated from the blocks  $(1, y, 192, 10)$ , the  $y$  taking values in the range  $400, \dots, 600$  increasing each time by 5. Data from all adjacent lateral image lines in the block were concatenated to

**FIGURE 6.3** (a) Original image, (b) HOS-based deconvolution, (c) SOS-based deconvolution. In all cases the logarithm of the envelope is displayed. Autocovariance plots for (d) original, (e) HOS deconvolved, and (f) SOS deconvolved RF data.

make a long one-dimensional vector. Note that  $N_y = 10$  corresponds to a very small depth, 0.4 mm in the real tissue space, hence the underlying assumption that the lateral distortion kernel does not vary much over this depth, should be reasonable.

Figure 6.3b,c show that the result of lateral followed by axial deconvolution of the image of Figure 6.3a, using respectively HOS- and SOS-based distortion kernel estimates. The deconvolution was performed via the constrained Wiener Filter technique [58]. According to Figure 6.3, the deconvolution in the RF-domain resulted in a significant reduction in speckle size. The speckle size appears smaller in the HOS-deconvolved image than in SOS-deconvolved ones, which is evidence of higher resolution. The resolution improvement can be quantified based on the width of the main lobe of the autocovariance of the image. The axial resolution gain for the HOS-based approach was 1.8 times that of the SOS-based approach. The lateral resolution gain for the HOS-based approach was 1.73 times as much. From a radiologist's point of view, overall, the HOS image appears to have better spatial resolution than the original as well as the SOS deconvolved images. Conversely, the SOS image seems to have incurred a loss of both axial and lateral resolution.

## Acknowledgments

Parts of this chapter have been based on the book: Nikias, C.L. and Petropulu, A.P., Higher Order Spectral Analysis: A Nonlinear Signal Processing Framework, Prentice Hall, Englewood Cliffs, NJ, 1993.

Major support for this work came from the National Science Foundation under grant MIP-9553227, the Whitaker Foundation, the National Institute of Health under grant 2P01CA52823-07A1, Drexel University and the Laboratoire des Signaux et Systems, CNRS, Universite Paris Sud, Ecole Superieure d'Electric, France.

The author would like to thank Drs. F. Forsberg and E. Conant for providing the ultrasound image and for evaluating the processed image.

Computing with neural networks (NNs) is one of the faster growing fields in the history of artificial intelligence (AI), largely because NNs can be trained to identify nonlinear patterns between input and output values and can solve complex problems much faster than digital computers. Owing to their wide range of applicability and their ability to learn complex and nonlinear relationships — including noisy or less precise information — NNs are very well suited to solving problems in biomedical engineering and, in particular, in analyzing biomedical signals.

Neural networks have made strong advances in continuous speech recognition and synthesis, pattern recognition, classification of noisy data, nonlinear feature detection, and other fields. By their nature, NNs are capable of high-speed parallel signal processing in real time. They have an advantage over conventional technologies because they can solve problems that are too complex — problems that do not have an algorithmic solution or for which an algorithmic solution is too complex to be found. NNs are trained by example instead of rules and are automated. When used in medical diagnosis, they are not affected by factors such as human fatigue, emotional states, and habituation. They are capable of rapid identification, analysis of conditions, and diagnosis in real time.

The most widely used architecture of an NN is that of a multilayer perceptron (MLP) trained by an algorithm called backpropagation (BP). Backpropagation is a gradient-descent algorithm that tries to minimize the average squared error of the network. In real applications, the network is not a simple one-dimensional system, and the error curve is not a smooth, bowl-shaped curve. Instead, it is a highly complex, multidimensional curve with hills and valleys (for a mathematical description of the algorithm).

BP was first developed by Werbos in 1974 [1], rediscovered by Parker in 1982 [2], and popularized later by Rummelhart et al. in 1986 [3]. There exist many variations of this algorithm, especially trying

to improve its speed and performance in avoiding getting stuck into local minima — one of its main drawbacks.

In my work, I use the ALOPEX algorithm developed by my colleagues and myself (see Chapter 182) [4–10], and my colleagues and I have applied it in a variety of world problems of considerable complexity. This chapter will examine several applications of NNs in biomedical signal processing. One- and two-dimensional signals are examined.

## 7.1 Neural Networks in Sensory Waveform Analysis

---

Mathematical analysis of the equations describing the processes in NNs can establish any dependencies between quantitative network characteristics, the information capacity of the network, and the probabilities of recognition and retention of information. It has been proposed that electromyographic (EMG) patterns can be analyzed and classified by NNs [11] where the standard BP algorithm is used for decomposing surface EMG signals into their constituent action potentials (APs) and their firing patterns [12]. A system such as this may help a physician in diagnosing time-behavior changes in the EMG.

The need for a knowledge-based system using NNs for evoked potential recognition was described by Bruha and Madhavan [13]. In this chapter, the authors used syntax pattern-recognition algorithms as a first step, while a second step included a two-layer perceptron to process the list of numerical features produced by the first step.

Myoelectric signals (MES) also have been analyzed by NNs [14]. A discrete Hopfield network was used to calculate the time-series parameters for a moving-average MES. It was demonstrated that this network was capable of producing the same time-series parameters as those produced by a conventional sequential least-squares algorithm. In the same paper, a second implementation of a two-layered perceptron was used for comparison. The features used were a time-series parameter and the signal power in order to train the perceptron on four separate arm functions, and again, the network performed well.

Moving averages have been simulated for nonlinear processes by the use of NNs [15]. The results obtained were comparable with those of linear adaptive techniques.

Moody et al. [16] used an adaptive approach in analyzing visual evoked potentials. This method is based on spectral analysis that results in spectral peaks of uniform width in the frequency domain. Tunable data windows were used. Specifically, the modified Bessel functions  $I_0 - \sin h$ , the gaussian, and the cosine-taper windows are compared. The modified Bessel function window proved to be superior in classifying normal and abnormal populations.

Pulse-transmission NNs — networks that consist of neurons that communicates with other neurons via pulses rather than numbers — also have been modeled [7,17]. This kind of network is much more realistic, since, in biological systems, action potentials are the means of neuronal communication. Dayhoff [18] has developed a pulse-transmission network that can temporally integrate arriving signals and also display some resistance to temporal noise.

Another method is optimal filtering, which is a variation of the traditional matched filter in noise [19]. This has the advantage of separating even overlapping waveforms. It also carries the disadvantage that the needed knowledge of the noise power spectral density and the Fourier transform of the spikes might not be always available.

Principal-components analysis also has been used. Here the incoming spike waveforms are represented by templates given by eigenvectors from their average autocorrelation functions [20]. The authors found that two or three eigenvectors are enough to account for 90% of the total energy of the signal. This way each spike can be represented by the coordinates of its projection onto the eigenvector space. These coordinates are the only information needed for spike classification, which is further done by clustering techniques.

### 7.1.1 Multineuronal Activity Analysis

When dealing with single- or multineuron activities, the practice is to determine how many neurons (or units) are involved in the “spike train” evoked by some sensory stimulation. Each spike in a spike train

represents an action potential elicited by a neuron in close proximity to the recording electrode. These action potentials have different amplitudes, latencies, and shape configurations and, when superimposed on each other, create a complex waveform — a composite spike. The dilemma that many scientists face is how to decompose these composite potentials into their constituents and how to assess the question of how many neurons their electrode is recording from. One of the most widely used methods is window discrimination, in which different thresholds are set, above which the activity of any given neuron is assigned, according to amplitude. Peak detection techniques also have been used [21]. These methods perform well if the number of neurons is very small and the spikes are well separated. Statistical methods of different complexity also have been used [22–24] involving the time intervals between spikes. Each spike is assigned a unique instant of time so that a spike train can be described by a process of time points corresponding to the times where the action potential had occurred. Processes such as these are called point processes, since they are characterized by only one number. Given this, a spike train can be treated as a stochastic point process that may or may not be stationary. In the former case, its statistics do not vary in the time of observation [25]. In the second case, when nonstationarity is assumed, any kind of statistical analysis becomes formidable.

Correlations between spike trains of neurons can be found because of many factors, but mostly because of excitatory or inhibitory interactions between them or due to a common input to both. Simulations on each possibility have been conducted in the past [26]. In our research, when recording from the optic tectum of the frog, the problem is the reversed situation of the one given above. That is, we have the recorded signal with noise superimposed, and we have to decompose it to its constituents so that we can make inferences on the neuronal circuitry involved. What one might do would be to set the minimal requirements on a neural network, which could behave the same way as the vast number of neurons that could have resulted in a neural spike train similar to the one recorded.

This is a very difficult problem to attack with no unique solution. A method that has attracted attention is the one developed by Gerstein et al. [22,27]. This technique detects various functional groups in the recorded data by the use of the so-called gravitational clustering method. Although promising, the analysis becomes cumbersome due to the many possible subgroups of neurons firing in synchrony. Temporal patterns of neuronal activity also have been studied with great interest. Some computational methods have been developed for the detection of favored temporal patterns [28–31]. My group also has been involved in the analysis of complex waveforms by the development of a novel method, the ST-scan method [32]. This method is based on well-known tomographic techniques, statistical analysis, and template matching. The method proved to be very sensitive to even small variations of the waveforms due to the fact that many orientations of them are considered, as it is done in tomographic imaging. Each histogram represents the number of times a stroke vector at a specific orientation is cutting the composite waveform positioned at the center of the window. These histograms were then fed to a NN for categorization. The histograms are statistical representations of individual action potentials. The NN therefore must be able to learn to recognize histograms by categorizing them with the action potential waveform that they represent. The NN also must be able to recognize any histogram as belonging to one of the “learned” patterns or not belonging to any of them [33]. In analyzing the ST-histograms, the NN must act as an “adaptive demultiplexer.” That is, given a set of inputs, the network must determine the correspondingly correct output. This is a categorization procedure performed by a perceptron, originally described by Rosenblatt [34]. In analyzing the ST-histograms, the preprocessing is done by a perceptron, and the error is found either by an LMS algorithm [35] or by an ALOPEX algorithm [36–38].

### 7.1.2 Visual Evoked Potentials

Visual evoked potentials (VEPs) have been used in the clinical environment as a diagnostic tool for many decades. Stochastic analysis of experimental recordings of VEPs may yield useful information that is not well understood in its original form. Such information may provide a good diagnostic criterion in differentiating normal subjects from subjects with neurological diseases as well as provide an index of the progress of diseases.

These potentials are embedded in noise. Averaging is then used in order to improve the signal-to-noise (S/N) ratio. When analyzing these potentials, several methods have been used, such as spectral analysis of their properties [39], adaptive filtering techniques [40,41], and some signal enhancers, again based on adaptive processes [42]. In this latter method, no a priori knowledge of the signal is needed. The adaptive signal enhancer consists of a bank of adaptive filters, the output of which is shown to be a minimum mean-square error estimate of the signal.

If we assume that the VEP represents a composite of many action potentials and that each one of these action potentials propagates to the point of the VEP recording, the only differences between the various action potentials are their amplitudes and time delays. The conformational changes observed in the VEP waveforms of normal individuals and defected subjects can then be attributed to an asynchrony in the arrival of these action potentials at a focal point (integration site) in the visual cortex [36]. One can simulate this process by simulating action potentials and trying to fit them to normal and abnormal VEPs with NNs.

Action potentials were simulated using methods similar to those of Moore and Ramon [43] and Bell and Cook [44]. Briefly, preprocessing of the VEP waveforms is done first by smoothing a five-point filter that performs a weighted averaging over its neighboring points

$$S(n) = [F(n-2) + 2F(n-1) + 3F(n) + 2F(n+1) + F(n+2)]/9 \quad (7.1)$$

The individual signals  $v_j$  are modulated so that at the VEP recording site each  $v_j$  has been changed in amplitude  $am(j)$  and in phase  $ph(j)$ . The amplitude change represents the propagation decay, and the phases represent the propagation delays of signals according to the equation

$$v_j(i) = am(j) \cdot AP[i - ph(j)] \quad (7.2)$$

For a specific choice of  $am(j)$  and  $ph(j)$ ,  $j = 1, 2, \dots, N$ , the simulated VEP can be found by

$$VEP = b + k \sum_{j=1}^N v_j^\alpha \quad (7.3)$$

where  $k$  is a scaling factor,  $b$  is a d.c. component, and  $\alpha$  is a constant [37,38].

The ALOPEX process was used again in order to adjust the parameters (amplitude and phase) so that the cost function reaches a minimum and therefore the calculated waveform coincides with the experimental one.

The modified ALOPEX equation is given by

$$p_i(n) = p_i(n-1) + \gamma \Delta p_i(n) \Delta R(n) + \mu r_i(n) \quad (7.4)$$

where  $p_i(n)$  are the parameters at iteration  $n$ , and  $\gamma$  and  $\mu$  are scaling factors of the deterministic and random components, respectively, which are adjusted so that at the beginning  $\gamma$  is small and  $\mu$  is large. As the number of iterations increases,  $\gamma$  increases while  $\mu$  decreases. The cost function  $R$  is monitored until convergence has been achieved at least 80% or until a preset number of iterations has been covered.

The results obtained show a good separation between normal and abnormal VEPs. This separation is based on an index  $\lambda$ , which is defined as the ratio of two summations, namely, the summation of amplitudes whose  $ph(i)$  is less than 256 msec and the summation of amplitudes whose  $ph(i)$  is greater than 256 msec. A large value of  $\lambda$  indicates an abnormal VEP, while a small  $\lambda$  indicates a normal VEP.

The convergences of the process for a normal and an abnormal VEP are shown in Figure 7.1 and Figure 7.2, respectively, at different iteration numbers. The main assumption here is that in normal individuals, the action potentials all arrive at a focal point in the cortex in resonance, while in abnormal subjects there exists asynchrony of the arrival times. Maier and colleagues [45] noted the importance of

**FIGURE 7.1** Normal VEP. (a) The fitting at the beginning of the process, (b) after 500 iterations, and (c) after 1000 iterations. Only one action potential is repeated 1000 times. The  $x$ -axis is  $\times 10$  msec; the  $y$ -axis is in millivolts.

source localization of VEPs in humans in studying the perceptual behavior in humans. The optimization procedure used in this section can help that task, since individual neuronal responses are optimally isolated. One of the interesting points is that signals (action potentials) with different delay times result in composite signals of different forms. Thus the reverse solution of this problem, that is, extracting individual signals from a composite measurement, can help resolve the problem of signal source localization. The multiunit recordings presented in the early sections of this paper fall in the same category with that of decomposing VEPs. This analysis might provide insight as to how neurons communicate.

## 7.2 Neural Networks in Speech Recognition

Another place where NNs find wide application is in speech recognition. Tebelski et al. [46] have studied the performance of linked predictive NNs (LPNNs) for large-vocabulary, continuous-speech recognition. The authors used a six-state phoneme topology, and without any other optimization, the LPNN achieved an average of 90, 58, and 39% accuracy on tasks with perplexity of 5, 11, and 402, respectively, which is better than the performance of several other simpler NNs tested. These results show that the main advantages of predictive networks are mainly that they produce nonbinary distortion measures in a simple way and that they can model dynamic properties such as those found in speech. Their weakness is that they show poor discrimination, which may be corrected by corrective training and function work modeling.

**FIGURE 7.2** Abnormal VEP. (a) Fitting at  $t = 3$  iterations, (b) after 500 iterations, and (c) after 2000 iterations. One action potential was used 1000 times.

Allen and Kanam [47] designed in NN architecture that locates word boundaries and identifies words from phoneme sequences. They tested the model in three different regimes with a highly redundant corpus and a restricted vocabulary, and the NN was trained with a limited number of phonemic variations for the words in the corpus. These tests yielded a very low error rate. In a second experiment, the network was trained to identify words from expert transcriptions of speech. The error rate for correct simultaneous identification of words and word boundaries was 18%. Finally, they tested the use of the output of a phoneme classifier as the input to the word and word boundary identification network. The error rate increased almost exponentially to 49%.

The best discrimination came from hybrid systems such as the use of an MLP and a hidden Markov model (HMM). These systems incorporate multiple sources of evidence such as features and temporal context without any restrictive assumptions of distributions or statistical independence. Bourland et al. [48] used MLPs as linear predictions for autoregressive HMMs. This approach, although more compatible with the HMM formalism, still suffers from several limitations. Although these authors generalized their approach to take into account time correlations between successive observations without any restrictive assumptions about the driving noise, the reputed results show that many of the tricks used to improve standard HMMs are also valid for this hybrid approach.

In another study, Intrator [49] used an unsupervised NN for dimensionality reduction that seeks directions emphasizing multimodality and derived a new statistical insight to the synaptic modification equations learning as in the Bienenstock, Cooper, and Munro (BCM) neurons [50]. The speech data consisted of 20 consecutive time windows of 32 msec with 30-msec overlap aligned at the beginning of the time. For each window, a set of 22 energy levels was computed corresponding to the Zwicker critical-band

filters [51]. The classification results were compared with those of a backpropagation network. These results showed that the backpropagation network does well in finding structures useful for classification of the trained data, but these structures are more sensitive to voicing. Classification results using a BCM network, on the other hand, suggest that for the specified task, structures that are more sensitive to voicing can be extracted, even though voicing imposes several effects on the speech signal. These features are more speaker-invariant.

Phan et al. [52] have attempted to solve the “cocktail party effect,” which describes phenomena in which humans can selectively focus attention on one sound source among competing sound sources. This is an ability that is hampered for the hearing-impaired. A system was developed that successfully identifies a speaker in the presence of competing speakers for short utterances. Features used for identification are monaural, whose feature space represent a 90% data reduction from the original data. This system is presently used off-line and also has been applied successfully to intraspeaker speech recognition. The features used in the preprocessing were obtained by wavelet analysis. This multiresolution analysis decomposes a signal into a hierarchical system of subspaces that are one-dimensional and are square integrable. Each subspace is spanned by basis functions that have scaling characteristics of either dilation or compression depending on the resolution. The implementation of these basis functions is incorporated in a recursive pyramidal algorithm in which the discrete approximation of a current resolution is convolved with quadrature mirror filters in the subsequent resolution [53]. After preprocessing, speech waveform is analyzed by the wavelet transform. Analysis is limited to four octaves. For pattern-recognition input configuration, the wavelet coefficients are mapped to a vector and used as inputs to a neural network trained by the ALOPEX algorithm. White noise was superimposed on the features as well in order to establish a threshold of robustness of the algorithm.

### 7.3 Neural Networks in Cardiology

---

Two-dimensional echocardiography is an important noninvasive clinical tool for cardiac imaging. The endocardial and epicardial boundaries of the left ventricle (LV) are very useful quantitative measures of various functions of the heart. Cardiac structures detection in ECG images is very important in recognizing the image parts.

A lot of research in the last couple of years has taken place around these issues and the application of neural networks in solving them. Hunter et al. [54] have used NNs in detecting echocardiographic LV boundaries and the center of the LV cavity. The points detected are then linked by a “snake” energy-minimizing function to give the epicardial and endocardial boundaries. A snake is an energy-minimizing deformable curve [55] fined by an internal energy that is the controller of the differential properties in terms of its curvature and its metrics. The most robust results were obtained by a  $9 \times 9$  square input vector with a resolution reduction of 32 : 1. Energy minimization is carried out by simulated annealing. The minimum energy solution was obtained after 1000 iterations over the entire snake. The use of NNs as edge detectors allows the classification of points to be done by their probability of being edges rather than by their edge strength, a very important factor for echocardiographic images due to their wide variations in edge strength.

A complex area in electrocardiography is the differentiation of wide QRS tachycardias in ventricular (VT) and supraventricular tachycardia (SVT). A set of criteria for this differentiation has been proposed recently by Brugada et al. [56]. One important aspect of applying NNs in interpreting ECGs is to use parameters that not only make sense but are also meaningful for diagnosis. Dassen et al. [57] developed an induction algorithm that further improved the criteria set by Brugada et al., also using NNs.

Nadal and deBossan [58] used principal-components analysis (PCA) and the relative *R*-wave to *R*-wave intervals of *P*-QRS complexes to evaluate arrhythmias. Arrhythmias are one of the risks of sudden cardiac arrest in coronary care units. In this study, the authors used the first 10 PCA coefficients (PCCs) to reduce the data of each *P*-QRS complex and a feedforward NN classifier that splits the vector space generated by the PCCs into regions that separate the different classes of beats in an efficient way. They obtained better

classification than using other methods, with correct classification of 98.5% for normal beats, 98.5% for ventricular premature beats, and 93.5% for fusion beats, using only the first two PCCs. When four PCCs were used, these classifications improved to 99.2, 99.1, and 94.1%, respectively. These results are better than those obtained by logistic regression when the input space is composed of more than two classes of beats. The difficulties encountered include the elimination of redundant data in order not to overestimate the importance of normal beat detection by the classifier.

In another work, Silipo et al. [59] used an NN as an autoassociator. In previous work they had proved that NNs had better performances than the traditional clustering and statistical methods. They considered beat features derived from both morphologic and prematurity information. Their classification is adequate for ventricular ectopic beats, but the criteria used were not reliable enough to characterize the supraventricular ectopic beat.

A lot of studies also have used NNs for characterization of myocardial infarction (MI). Myocardial infarction is one of the leading causes of death in the United States. The currently available techniques for diagnosis are accurate enough, but they suffer from certain drawbacks, such as accurate quantitative measure of severity, extent, and precise location of the infarction. Since the acoustic properties in the involved region are mostly changing, one can study them by the use of ultrasound.

Baxt [60] used an NN to identify MI in patients presented to an emergency department with anterior chest pain. An NN was trained on clinical pattern sets retrospectively derived from patients hospitalized with a high likelihood of having MI, and the ability of the NN was compared with that of physicians caring for the same patients. The network performed with a sensitivity of 92% and a specificity of 96%. These figures were better than the physicians, with a sensitivity of 88% and a specificity of 71%, or any other computer technology (88% sensitivity, 74% specificity) [61].

Diagnosis of inferior MI with NNs was studied by Hedén et al. [62] with sensitivity of 84% and a specificity of 97%, findings that are similar to those of Pahlm et al. [63].

Yi et al. [64] used intensity changes in an echocardiogram to detect MI. Once an echocardiogram is obtained, it is digitized and saved in a file as a gray-scale image (512 × 400) (Figure 7.3). A window of the region of interest is then selected between the systole and diastole of the cardiac cycle and saved in a different file. The window can be either of a constant size or it can be adaptive (varying) in size. This new file can be enlarged (zoom) for examination of finer details in the image. All image artifacts are filtered out, and contrast enhancement is performed. This new image is then saved and serves as input to the NN. A traditional three-layer NN with 300 input nodes (one node for each pixel intensity in the input file), a varying number of hidden nodes, and two output nodes were used. The output node indicates the status of the patient under testing. A “one” indicates normal and a “zero” an abnormal case.

**FIGURE 7.3** Selection of region of interest. The intensity pattern in the box is used as input to the NN.

The weights of the connections were calculated using the optimization algorithms of ALOPEX. One sub-ALOPEX was used for the weights between hidden nodes and input nodes, and a second sub-ALOPEX was used for those from the output to the hidden layer.

The network was trained with a population of 256 patients, some with scars and some normal. These patients were used to obtain “templates” for each category. These templates were then used for comparison with the test images. None of these testing images was included in the training set. The cost function used for the process was the least-squares rule, which, although slow, produces reliable results.

A similar process is used for the output layer. The noise was made adaptable. The intensities of the images are normalized before being submitted to the NN. A cutoff of 0.2 was used. Therefore, anything above 0.8 is normal, below 0.2 is scar, and all the in-between values are classified as unknown. Due to the fact that the scar training set was very small compared with the normals, a better classification of normals than scars was observed. A study was also made as to how the number of hidden nodes influences the results for the same standard deviation of noise.

In another study, Kostis et al. [65] used NNs in estimating the prognosis of acute MI. Patients who survive the acute phase of an MI have an increased risk of mortality persisting up to 10 years or more. Estimation of the probability of being alive at a given time in the future is important to the patients and their physicians and is usually ascertained by the use of statistical methods. The purpose of the investigation was to use an NN to estimate future mortality of patients with acute MI. The existence of a large database (Myocardial Infarction Data Acquisition Systems, or MIDAS) that includes MI occurring in the state of New Jersey and has long-term follow-up allows the development and testing of such a computer algorithm. Since the information included in the database does not allow the exact prediction of vital status (dead or alive) in all patients with 100% accuracy, the NN should be able to categorize patients according to the probability of dying within a given period of time.

Since information included in the database is not sufficient to allow the exact prediction of vital status (dead or alive) in all patients with 100% accuracy, we developed an NN able to categorize patients according to the probability of dying within a given period of time rather than predicting categorically whether a patient will be dead or alive at a given time in the future. It was observed that there were many instances where two or more patients had identical input characteristics while some were dead and some alive at the end of the study period. For this reason, it is difficult to train a standard NN. Since there is no unique output value for all input cases, the network had difficulty converging to a unique set of solutions. To alleviate this problem, a conflict-resolution algorithm was developed. The algorithm takes templates with identical input vectors and averages each of their input characteristics to produce a single case. Their output values of vital status are averaged, producing, in effect, a percentage probability of mortality for the particular set of input characteristics. As each new subject template is read into the program, its input characteristics are compared with those of all previous templates. If no match is found, its input values and corresponding output value are accepted. If a match is found, the output value is brought together with the stored output value (percentage probability of mortality and the number of templates on which it is based), and a new output value is calculated, representing the percentage average mortality of the entire characteristic group. Since each member of the group is an identical input case, no input characteristic averaging is necessary, thus preserving the statistical significance of the average mortality with respect to that exact case.

This new algorithm, using the two-hidden-layer perceptron optimized by ALOPEX, has converged to greater than 98% using several thousand input cases. In addition, 10 output nodes were used in the final layer, each corresponding to a range of percent chance or mortality (e.g., node 1: 0 to 10%; node 2: 10 to 20%; etc.). The outputs of the network are designed to maximize one of the 10 potential output “binds,” each corresponding to a decile of mortality between 0 and 100%. The output node containing the correct probability value was set to a value of 1.0; the others to 0.0. In this manner, the network should be able to provide percentage probability of mortality and also to resolve input-case conflicts. An SAS program was written to present the predicted probability of mortality separately in patients who are dead or alive at the end of the follow-up period. The NNs constructed as described above were able to be trained and evaluated according to several definitions of network response: matching the output value at every output

**FIGURE 7.4** Recognition rate versus standardization of noise added to the inputs. Different curves correspond to various learning levels with damaged weights. (a) Noise added only to the inputs. (b) Noise added to the weights to mimic “brain damage,”  $s = 0.05$ . (c) Noise on the weights with  $s = 0.1$ . Notice how much more robust the “brain” is to noise with higher levels of education.

node, identifying the correct location of which node was to contain the peak output value, and matching the output value at the peak output location.

The network was tested on known and then on unknown cases. A correspondence of the observed to the predicted probability of being alive at a given time was observed. The categorical classifications (dead or alive) yielded an overall accuracy of 74%. A reciprocal relationship between sensitivity and specificity of the rules for determination of vital status was observed.

## 7.4 Neural Networks in Neurology

---

Neural networks found applications in neurology as well and, in particular, in characterizing memory defects, as are apparent in diseases such as Parkinson's and Alzheimer's. Both diseases exhibit devastating effects and disrupt the lives of those affected.

For several decades, in an attempt to further understand brain functions, computational neuroscientists have addressed the issue by modeling biologic neural network structure with computer simulations. A recent article by Stern et al. [66] reports on an important relationship of Alzheimer's disease expression and levels of education. A similar inverse relationship was earlier reported by Zhang et al. [67] in a Chinese population. This inverse relationship was attributed to a protective role of the brain reserve capacity [68]. Such a capacity becomes important, since in an educated person's brain more synapses exist, which might protect the individual in the expression of symptoms of the disease. It is not argued, however, that the disease will not be acquired; rather, that it will be delayed. Zahner et al. [69] have employed a three-layer feedforward NN trained with ALOPEX to simulate the effects of education in dementia, age-related changes, and in general, brain damage. Our results show that the higher the level of training of the NN, 50, 60, 70, 80%, etc., the slower is the damage on the "brain." Damage was simulated by systematically adding noise on the weights of the network. Noise had a gaussian distribution with varying standard deviations and mean of zero. Figure 7.4 shows the results of these simulations as recognition rate versus standard deviation of noise added to the inputs for increasingly damaged weights at various levels of training. Each point corresponds to an average of 100 samples. Notice how much slower the drop in recognition is for the 70 and 80% curves as compared with the 50 and 60% training. Also notice the distances of the starting points of the curves as we follow the progress of dementia at different stages (Figure 7.4, a vs. b vs. c). All curves demonstrate impairment with damage, but they also show some threshold in the training level, after which the system becomes more robust.

## 7.5 Discussion

---

Neural networks provide a powerful tool for analysis of biosignals. This chapter has reviewed applications of NNs in cardiology, neurology, speech processing, and brain waveforms. The literature is vast, and this chapter is by no means exhaustive. In the last 10 years, NNs have been used more and more extensively in a variety of fields, and biomedical engineering is not short of it. Besides the applications, a lot of research is still going on in order to find optimal algorithms and optimal values for the parameters used in these algorithms. In industry, an explosion of VLSI chip designs on NNs has been observed. The parallel character of NNs makes them very desirable solutions to computational bottlenecks.

**Complexity**, a contemporary theme embraced by physical as well as social sciences, is concerned with the collective behavior observed in composite systems in which long-range order is induced by short-range interactions of the constituent parts. Complex forms and functions abound in nature. Particularly in biology and physiology, branched, nested, granular, or otherwise richly packed, irregular, or disordered objects are the rule rather than the exception. Similarly ubiquitous are distributed, broad-band phenomena that appear to fluctuate randomly. The rising science of complexity holds the promise to lead to powerful tools to analyze, model, process, and control the global behavior of complex biomedical systems.

The basic tenets of the complexity theory rest on the revelation that large classes of complex systems (composed of a multitude of richly interacting components) are reducible to simple rules. In particular, the structure and dynamics of complex systems invariably exist or evolve over a multitude of spatial and temporal scales. Moreover, they exhibit a systematic relationship between scales. From the biomedical engineering standpoint, the worthwhile outcome is the ability to characterize these intricate objects and processes in terms of straightforward **scaling** and **fractal** concepts and measures that often can be translated into simple iterative rules. In this sense, the set of concepts and tools, emerging under the rubric of complexity, complements the prediction made by the **chaos** theory that simple (low-order deterministic) systems may generate complex behavior.

In their many incarnations, the concepts of complexity and scaling are playing a refreshingly unifying role among diverse scientific pursuits; therein lie compelling opportunities for scientific discoveries and technical innovations. Since these advances span a host of disciplines, hence different scientific languages, cultures, and dissemination media, finding one's path has become confusing. One of the aims of this presentation is to serve as a resource for key literature. We hope to guide the reader toward substantial contributions and away from figments of fascination in the popular press that have tended to stretch emerging concepts ahead of the rigorous examination of evidence and the scientific verification of facts.

This chapter is organized in three main parts. The first part is intended to serve as a primer for the fundamental aspects of the complexity theory. An overview of the attendant notions of scaling theories constitutes the core of the second part. In the third part, we illustrate the potential of the complexity approach by presenting an application to predict acceleration-induced loss of consciousness in pilots.

## 8.1 Complex Dynamics

---

There exists a class of systems in which very complex spatial and temporal behavior is produced through the rich interactions among a large number of local subsystems. Complexity theory is concerned with systems that have many degrees of freedom (composite systems), are spatially extended (systems with both spatial and temporal degrees of freedom), and are dissipative as well as nonlinear due to the interplay among local components (agents). In general, such systems exhibit **emergent global behavior**. This means that macroscopic characteristics cannot be deduced from the microscopic characteristics of the elementary components considered in isolation. The global behavior emerges from the interactions of the local dynamics.

Complexity theories draw their power from recognition that the behavior of a complex dynamic system does not, in general, depend on the physical particulars of the local elements but rather on how they interact to collectively (cooperatively or competitively) produce the globally observable behavior. The local agents of a complex dynamic system interact with their neighbors through a set of usually (very) simple rules.

The emergent global organization that occurs through the interplay of the local agents arises without the intervention of a central controller. That is, there is **self-organization**, a spontaneous emergence of global order. Long-range correlations between local elements are not explicitly defined in such models, but they are induced through local interactions. The global organization also may exert a top-down influence on the local elements, providing feedback between the macroscopic and microscopic structures [Forrest, 1990] (Figure 8.1).

### 8.1.1 Overcoming the Limits of Newtonian Mathematics

Linearity, as well as the inherent predictive ability, was an important factor in the success of Newtonian mechanics. If a linear system is perturbed by a small amount, then the system response will change by a proportionally small amount. In nonlinear systems, however, if the system is perturbed by a small amount, the response could be no change, a small change, a large change, oscillations (limit cycle), or chaotic behavior. The response depends on the state of the system at the time it was perturbed. Since most of nature is nonlinear, the key to success in understanding nature lies in embracing this nonlinearity.

Another feature found in linear systems is the property of superposition. Superposition means that the whole is equal to the sum of the parts. All the properties of a linear system can be understood through the analysis of each of its parts. This is not the case for complex systems, where the interaction among simple local elements can produce complex emergent global behavior.

Complexity theory stands in stark contrast to a purely reductionist approach that would seek to explain global behavior by breaking down the system into its most elementary components. The reductionist approach is not guaranteed to generate knowledge about the behavior of a complex system, since it is likely that the information about the local interactions (which determine the global behavior) will not be revealed in such an analysis. For example, knowing everything there is to know about a single ant will

FIGURE 8.1 A complex dynamic system.

reveal nothing about why an ant colony is capable of such complex behaviors as waging war, farming, husbandry, and the ability to quickly adapt to changing environmental conditions. The approach that complexity theory proposes is to look at the system as a whole and not merely as a collection of irreducible parts.

Complexity research depends on digital computers for simulation of interactions. **Cellular automata** (one of the principal tools of complexity) have been constructed to model sand piles, earthquakes, traffic patterns, satellite communication networks, evolution, molecular autocatalysis, forest fires, and species interactions (among others) [Toffoli and Margoulis, 1987]. We note here that complexity is building on, and in some cases unifying, developments made in the fields of chaotic dynamics [Devaney, 1992], critical phenomena, **phase transitions**, **renormalization** [Wilson, 1983], **percolation** [Stauffer and Aharony, 1992], neural networks [Harvey, 1994; Simpson, 1990], genetic algorithms [Goldberg, 1989] and artificial life [Langton, 1989; Langton et al., 1992].

### 8.1.2 Critical Phenomena: Phase Transitions

For the purpose of this discussion, a phase transition can be defined as any abrupt change between the physical and/or dynamic states of a system. The most familiar examples of phase transitions are between the fundamental stages of matter: solid, liquid, gas, and plasma. Phase transitions are also used to define other changes in matter, such as changes in the crystalline structure or state of magnetism. There are also phase transitions in the dynamics of systems from ordered (fixed-point and limit-cycle stability) to disordered (chaos). Determining the state of matter is not always straightforward. Sometimes the apparent state of matter changes when the scale of the observation (macroscopic versus microscopic) is changed. A critical point is a special case of phase transitions where order and disorder are intermixed at all scales [Wilson, 1983]. At **criticality**, all spatial and temporal features become scale invariant or self-similar. Magnetism is a good example of this phenomenon.

### 8.1.3 An Illustration of Critical Phenomena: Magnetism

The atoms of a ferromagnetic substance have more electrons with spins in one direction than in the other, resulting in a net magnetic field for the atom as a whole. The individual magnetic fields of the atoms tend to line up in one direction, with the result that there is a measurable level of magnetism in the material. At a temperature of absolute zero, all the atomic dipoles are perfectly aligned. At normal room temperature, however, some of the atoms are not aligned to the global magnetic field due to thermal fluctuations. This creates small regions that are nonmagnetic, although the substance is still magnetic. Spatial renormalization, or coarse graining, is the process of averaging the microscopic properties of the substance over a specified range in order to replace the multiple elements with a single equivalent element.

If measurements of the magnetic property were taken at a very fine resolution (without renormalization), there would be some measurements that detect small pockets of nonmagnetism, although most measurements would indicate that the substance was magnetic. As the scale of the measurements is increased, that is, spatially renormalized, the small pockets of nonmagnetism would be averaged out and would not be measurable. Therefore, measurements at the larger scale would indicate that the substance is magnetic, thereby decreasing its apparent temperature and making the apparent magnetic state dependent on the resolution of the measurements. The situation is similar (but reversed) at high temperatures. That is, spatial renormalization results in apparently higher temperatures, since microscopic islands of magnetism are missed because of the large areas of disorder in the material.

At the Curie temperature there is long-range correlation in both the magnetic and nonmagnetic regions. The distribution of magnetic and nonmagnetic regions is invariant under the spatial renormalization transform. These results are independent of the scale at which the measure is taken, and the apparent temperature does not change under the renormalization transform. This scale invariance (**self-similarity**) occurs at only three temperatures: absolute zero, infinity, and the Curie temperature. The Curie temperature represents a critical point (criticality) in the tuning parameter (temperature) that governs the phase transition from a magnetic to a nonmagnetic state [Pietgen and Richter, 1986].

### 8.1.4 A Model for Phase Transitions: Percolation

A percolation model is created by using a simple regular geometric framework and by establishing simple interaction rules among the elements on the grid. Yet these models give rise to very complex structures and relationships that can be described by using scaling concepts such as fractals and power laws. A percolation model can be constructed on any regular infinite  $n$ -dimensional lattice [Stauffer and Aharony, 1992]. For simplicity, the example discussed here will use a two-dimensional finite square grid. In site percolation, each node in the grid has only two states, occupied or vacant. The nodes in the lattice are populated based on a uniform probability distribution, independent of the state of any other node. The probability of a node being occupied is  $p$  (and thus the probability of a node being vacant is  $1 - p$ ). Nodes that are neighbors on the grid link together to form clusters (Figure 8.2).

Clusters represent connections between nodes in the lattice. Anything associated with the cluster can therefore travel (flow) to any node that belongs to the cluster. Percolation can describe the ability of water to flow through a porous medium such as igneous rock, oil fields, or finely ground Colombian coffee. As the occupation probability increases, the clusters of the percolation network grow from local connectedness to global connectedness [Feder, 1988]. At the critical occupation probability, a cluster that spans the entire lattice emerges. It is easy to see how percolation could be used to describe such phenomena as phase transitions by viewing occupied nodes as ordered matter, with vacant nodes representing disordered matter. Percolation networks have been used to model magnetism, forest fires, and the permeability of ion channels in cell membranes.

### 8.1.5 Self-Organized Criticality

The concept of self-organized criticality has been introduced as a possible underlying principle of complexity [Bak et al., 1988; Bak and Chen, 1991]. The class of self-organized critical systems is spatially extended, composite, and dissipative with many locally interacting degrees of freedom. These systems have the capability to naturally evolve (i.e., there is no explicit tuning parameter such as temperature or pressure) toward a critical state.

Self-organized criticality is best illustrated by a sand pile. Start with a flat plate. Begin to add sand one grain at a time. The mound will continue to grow until criticality is reached. This criticality is dependent only on the local interactions among the grains of sand. The local slope determines what will happen if another grain of sand is added. If the local slope is below the criticality (i.e., flat) the new grain of sand will stay put and increase the local slope. If the local slope is at the criticality, then adding the new grain of sand will increase the slope beyond the criticality, causing it to collapse. The collapsing grains of sand spread

FIGURE 8.2 A percolation network.

to adjoining areas. If those areas are at the criticality, then the avalanche will continue until local areas with slopes below the criticality are reached. Long-range correlations (up to the length of the sand pile) may emerge from the interactions of the local elements. Small avalanches are very common, while large avalanches are rare. The size (and duration) of the avalanche plotted against the frequency of occurrence of the avalanche can be described by a power law [Bak et al., 1988]. The sand pile seeks the criticality on its own. The slope in the sand pile will remain constant regardless of even the largest avalanches. These same power laws are observed in traffic patterns, earthquakes, and many other complex phenomena.

### 8.1.6 Dynamics at the Edge of Chaos

The dynamics of systems can be divided into several categories. Dynamic systems that exhibit a fixed-point stability will return to their initial state after being perturbed. A periodic evolution of states will result from a system that exhibits a limit-cycle stability. Either of these systems may display a transient evolution of states before the stable regions are reached. Dynamic systems also may exhibit chaotic behavior. The evolution of states associated with chaotic behavior is aperiodic, well-bounded, and very sensitive to initial conditions and resembles noise but is completely deterministic [Tsonis and Tsonis, 1989].

The criticality that lies between highly ordered and highly disordered dynamics has been referred to as the edge of chaos [Langton, 1990] and is analogous to a phase transition between states of matter, where the highly ordered system can be thought of as a solid and the highly disordered system a liquid.

The edge of chaos is the critical boundary between order and chaos. If the system dynamics are stagnant (fixed-point stability, highly ordered system), then there is no mechanism for change. The system cannot adapt and evolve because new states cannot be encoded into the system. If the system dynamics are chaotic (highly disordered), then the system is in a constant state of flux, and there is no memory, no learning, and no adaptation (some of the main qualities associated with life). Systems may exhibit transients in the evolution of states before settling down into either fixed-point or limit-cycle behavior. As the dynamics of a complex system enter the edge of chaos region, the length of these transients quickly grows. The chaotic region is where the length of the “transient” is infinite. At the edge of chaos (the dynamic phase transition) there is no characteristic scale due to the emergence of arbitrarily long correlation lengths in

space and time [Langton, 1990]. The self-organized criticality in the sand piles of Per Bak is an example of a system that exists at the edge of chaos. It is in this region that there is no characteristic space or time scale. A single grain of sand added to the pile could cause an avalanche that consists of two grains of sand, or it could cause an avalanche that spreads over the entire surface of the sand pile.

## 8.2 Introduction to Scaling Theories

---

Prior to the rise of complexity theories, the existence of a systematic relationship between scales eluded the mainstream sciences. As a consequence, natural structures and dynamics have been commonly dismissed as too irregular and complex and often rejected as monstrous formations, intractable noise, or artifacts. The advent of scaling concepts [Mandelbrot, 1983] has uncovered a remarkable hierarchical order that persists over a significant number of spatial or temporal scales.

Scaling theories capitalize on scale-invariant symmetries exhibited by many natural broadband (i.e., multiscale) phenomena. According to the theory of self-organized criticality (see Section 8.1), this scaling order is a manifestation of dilation (compression) symmetries that define the organization inherent to complex systems which naturally evolve toward a critical state while dissipating energies on broad ranges of space and time scales. Long overlooked, this symmetry is now added to the repertoire of mathematical modeling concepts, which had included approaches based largely on displacement invariances under translation and/or rotation.

Many natural forms and functions maintain some form of exact or statistical invariance under transformations of scale and thus belong in the scaling category. Objects and processes that remain invariant under ordinary geometric similarity constitute the self-similar subset in this class.

Methods to capture scaling information in the form of simple rules that relate features on different scales are actively developed in many scientific fields [Barnsley, 1993]. Engineers are coping with scaling nature of forms and functions by investigating multiscale system theory [Basseville et al., 1992], multiresolution and multirate signal processing [Akansu and Hadad, 1992; Vaidyanathan, 1993], subband coding, wavelets, and filter banks [Meyer, 1993], and fractal compression [Barnsley and Hurd, 1993].

These emerging tools empower engineers to reexamine old data and to re-formulate the question at the root of many unresolved inverse problems — What can small patterns say about large patterns, and vice versa? They also offer the possibility to establish cause–effect relationships between a given physical (spatial) medium and the monitored dynamic (temporal) behavior that constitutes the primary preoccupation of diagnostic scientists.

### 8.2.1 Fractal Preliminaries

In the broadest sense, the noun or adjective fractal refers to physical objects or dynamic processes that reveal new details on space or time magnification. A staple of a truly fractal object or process is therefore the lack of characteristic scale in time or space. Most structures in nature are broadband over a finite range, covering at least a number of frequency decades in space or time. Scaling fractals often consist of a hierarchy or heterarchy of spatial or temporal structures in cascade and are often accomplished through recursive replication of patterns at finer scales. If the replication rule preserves scale invariance throughout the entity, such fractals are recognized as self-similar in either an exact or a statistical sense.

A prominent feature of fractals is their ability to pack structure with economy of resources, whether energy, space, or whatever other real estate. Fitting nearly infinite networks into finite spaces is just one such achievement. These types of fractals are pervasive in physiology, that is, the branching patterns of the bronchi, the cardiovascular tree, and the nervous tissue [West and Goldberger, 1987], which have the additional feature of being “fault tolerant” [West, 1990].

Despite expectations heightened by the colorful publicity campaign mounted by promoters of fractal concepts, it is advisable to view fractals only as a starting approximation in analyzing scaling shapes and fluctuations in nature. Fractal concepts are usually descriptive at a phenomenologic level without

pretense to reveal the exact nature of the underlying elementary processes. They do not offer, for that matter, conclusive evidence of whatever particular collective, coupled, or isolated repetitive mechanism that created the fractal object.

In many situations, the power of invoking fractal concepts resides in the fact that they bring the logic of constraints, whether in the form of asymmetry of motion caused by defects, traps, energy barriers, residual memories, irreversibility, or any other appropriate interaction or coupling mechanisms that hinder free random behavior. As discussed earlier, the spontaneous or forced organization and the ensuing divergence in correlations and coherences that emerges out of random behavior are presumably responsible for the irregular structures pervasive throughout the physical world.

More important, the versatility of fractal concepts as a magnifying tool is rooted in the facility to account for scale hierarchies and/or scale invariances in an exact or statistical sense. In the role of a scale microscope, they suggest a fresh look, with due respect to all scales of significance, at many structural and dynamic problems deemed thus far anomalous or insoluble.

## 8.2.2 Mathematical and Natural Fractals

The history of mathematics is rife with “pathologic” constructions of the iterated kind which defy the euclidian dimension concepts. The collection once included an assortment of anomalous dust sets, lines, surfaces, volumes, and other mathematical miscellenia mostly born out of the continuous yet nondifferentiable category of functions such as the Weierstrass series.

The feature unifying these mathematical creations with natural fractals is the fractional or integer dimensions distinct from the euclidian definition. Simply stated, a fractional dimension positions an object in between two integer dimensions in the euclidian sense, best articulated by the critical dimension in the Hausdorff-Besicovith derivation [Feder, 1988]. When this notion of dimension is pursued to the extreme and the dimension reaches an integer value, one is confronted with the counterintuitive reality of space-filling curves, volume-filling planes, etc. These objects can be seen readily to share intrinsic scaling properties with the nearly infinite networks accomplished by the branching patterns of bronchi and blood vessels and the intricate folding of the cortex.

A rewarding outcome afforded by the advent of scaling concepts is the ability to characterize such structures in terms of straightforward “scaling” or “dimension” measures. From these, simple iterative rules may be deduced to yield models with maximum economy (or minimum number) or parameters [Barnsley, 1993]. This principle is suspected to underlie the succinct, coding adopted by nature in order to store extensive information needed to create complex shapes and forms.

## 8.2.3 Fractal Measures

The measure most often used in the diagnosis of a fractal is the basic fractal dimension, which, in the true spirit of fractals, has eluded a rigorous definition embracing the entire family of fractal objects. The guiding factor in the choice of the appropriate measures is the recognition that most fractal objects scale self-similarly; in other words, they can be characterized by a measure expressed in the form of a power factor, or scaling exponent  $\partial$ , that links the change in the observed dependent quantity  $V$  to the independent variable  $x$  as  $V(x) \approx x^\partial$  [Falconer, 1990: 36]. Clearly,  $\partial$  is proportional to the ratio of the logarithm of  $V(x)$  and  $x$ , that is,  $\partial = \log V(x)/\log x$ . In the case of fractal objects,  $\partial$  is the scaling exponent in the fractal sense and may have a fractional value. In the final analysis, most scaling relationships can be cast into some form of a logarithmic dependence on the independent variable with respect to which a scaling property is analyzed, the latter also expressed on the logarithmic scale. A number of dimension formulas have been developed based on this observation, and comprehensive compilations are now available [Falconer, 1990; Feder, 1988].

One approach to formalize the concept of scale invariance utilizes the homogeneity or the renormalization principle given by  $f(m) = f(am)/b$ , where  $a$  and  $b$  are constants and  $m$  is the independent variable [West and Goldberger, 1987]. The function  $f$  that satisfies this relationship is referred as a scaling function.

The power-law function  $f(m) \approx mb$  is a prominent example in this category provided  $b = \log b / \log a$ . The usefulness of this particular scaling function has been proven many times over in many areas of science, including the thermodynamics of phase transitions and the threshold behavior of percolation networks [Schroeder, 1991; Stauffer and Aharony, 1992; Wilson, 1983].

### 8.2.4 Power Law and 1/f Processes

The revived interest in power-law behavior largely stems from the recognition that a large class of noisy signals exhibits spectra that attenuate with a fractional power dependence on frequency [West and Shlesinger, 1989; Wornell, 1993]. Such behavior is often viewed as a manifestation of the interplay of a multitude of local processes evolving on a spectrum of time scales that collectively give rise to the so-called 1/f or, more generally, the 1/f-type behavior. As in the case of spatial fractals that lack a characteristic length scale, **1/f processes** such as the **fractional brownian motion** cannot be described adequately within the confines of a “characteristic” time scale and hence exhibit the “fractal time” property [Mandelbrot, 1967].

### 8.2.5 Distributed Relaxation Processes

Since the later part of the nineteenth century, the fractional power function dependence of the frequency spectrum also has been recognized as a macroscopic dynamic property manifested by strongly interacting dielectric, viscoelastic, and magnetic materials and interfaces between different conducting materials [Daniel, 1967]. More recently, the 1/f-type dynamic behavior has been observed in percolating networks composed of random mixtures of conductors and insulators and layered wave propagation in heterogeneous media [Orbach, 1986]. In immittance (impedance or admittance) studies, this frequency dispersion has been analyzed conventionally to distinguish a broad class of the so-called anomalous, that is, nonexponential, relaxation/dispersion systems from those which can be described by the “ideal” single exponential form due to Debye [Daniel, 1967].

The fractal time or the multiplicity of times scales prevalent in distributed relaxation systems necessarily translates into fractional constitutive models amenable to analysis by fractional calculus [Ross, 1977] and fractional state-space methods [Bagley and Calico, 1991]. This corresponds to logarithmic distribution functions ranging in symmetry from the log-normal with even center symmetry at one extreme to single-sided hyperbolic distributions with diverging moments at the other. The realization that systems that do not possess a characteristic time can be described in terms of distributions renewed the interest in the field of dispersion/relaxation analysis. Logarithmic distribution functions have been used conventionally as means to characterize such complexity [West, 1994].

### 8.2.6 Multifractals

Fractal objects and processes in nature are rarely strictly homogeneous in their scaling properties and often display a distribution of scaling exponents that echos the structural heterogeneities occurring at a myriad of length or time scales. In systems with spectra that attenuate following a pure power law over extended frequency scales, as in the case of Davidson–Cole dispersion [Daniel, 1967], the corresponding distribution of relaxation times is logarithmic and single-tailed. In many natural relaxation systems, however, the spectral dimension exhibits a gradual dependence on frequency, as in phenomena conventionally modeled by the Cole–Cole type dispersion. The equivalent distribution functions exhibit double-sided symmetries on the logarithmic relaxation time scale ranging from the even symmetry of the log-normal through intermediate symmetries down to strictly one-sided functions.

The concept that a fractal structure can be composed of fractal subsets with uniform scaling property within the subset has gained popularity in recent years [Feder, 1988]. From this perspective, one may view a complicated fractal object, say, the strange attractor of a chaotic process, as a superposition of simple fractal subsystems. The idea has been formalized under the term multifractal. It follows that each individual member contributes to the overall scaling behavior according to a spectrum of scaling

exponents or dimensions. The latter function is called the multifractal spectrum and summarizes the global scaling information of the complete set.

### **8.3 An Example of the Use of Complexity Theory in the Development of a Model of the Central Nervous System**

---

Consciousness can be viewed as an emergent behavior arising from the interactions among a very large number of local agents, which, in this case, range from electrons through neurons and glial cells to networks of neurons. The hierarchical organization of the brain [Churchland and Sejnowski, 1992; Newell, 1990], which exists and evolves on a multitude of spatial and temporal scales, is a good example of the scaling characteristics found in many complex dynamic systems. There is no master controller for this emergent behavior, which results from the intricate interactions among a very large number of local agents.

A model that duplicates the global dynamics of the induction of unconsciousness in humans due to cerebral ischemia produced by linear acceleration stress (G-LOC) was constructed using some of the tenets of complexity [Cammarota, 1994]. It was an attempt to provide a theory that could both replicate historical human acceleration tolerance data and present a possible underlying mechanism. The model coupled the realization that an abrupt loss of consciousness could be thought of as a phase transition from consciousness to unconsciousness with the proposed neurophysiologic theory of G-LOC [Whinnery, 1989]. This phase transition was modeled using a percolation network to evaluate the connectivity of neural pathways within the central nervous system.

In order to construct the model, several hypotheses had to be formulated to account for the unobservable interplay among the local elements of the central nervous system. The inspiration for the characteristics of the locally interacting elements (the nodes of the percolation lattice) was provided by the physiologic mechanism of arousal (the all-or-nothing aspect of consciousness), the utilization of oxygen in neural tissue during ischemia, and the response of neural cells to metabolic threats. The neurophysiologic theory of acceleration tolerance views unconsciousness as an active protective mechanism that is triggered by a metabolic threat which in this case is acceleration-induced ischemia. The interplay among the local systems is determined by using a percolation network that models the connectivity of the arousal mechanism (the reticular activating system). When normal neuronal function is suppressed due to local cerebral ischemia, the corresponding node is removed from the percolation network. The configuration of the percolation network varies as a function of time. When the network is no longer able to support arousal, unconsciousness results.

The model simulated a wide range of human data with a high degree of fidelity. It duplicated the population response (measured as the time it took to lose consciousness) over a range of stresses that varied from a simulation of the acute arrest of cerebral circulation to a gradual application of acceleration stress. Moreover, the model was able to offer a possible unified explanation for apparently contradictory historical data. An analysis of the parameters responsible for the determination of the time of LOC indicated that there is a phase transition in the dynamics that was not explicitly incorporated into the construction of the model. The model spontaneously captured an interplay of the cardiovascular and neurologic systems that could not have been predicted based on existing data.

The keys to the model's success are the reasonable assumptions that were made about the characteristics and interaction of the local dynamic subsystems through the integration of a wide range of human and animal physiologic data in the design of the model. None of the local parameters was explicitly tuned to produce the global (input-output) behavior. By successfully duplicating the observed global behavior of humans under acceleration stress, however, this model provided insight into some (currently) unobservable inner dynamics of the central nervous system. Furthermore, the model suggests new experimental protocols specifically aimed at exploring further the microscopic interplay responsible for the macroscopic (observable) behavior.

## Defining Terms

- 1/f process:** Signals or systems that exhibit spectra which attenuate following a fractional power dependence on frequency.
- Cellular automata:** Composite discrete-time and discrete space dynamic systems defined on a regular lattice. Neighborhood rules determine the state transitions of the individual local elements (cells).
- Chaos:** A state that produces a signal that resembles noise and is aperiodic, well-bounded, and very sensitive to initial conditions but is governed by a low-order deterministic differential or difference equation.
- Complexity:** Complexity theory is concerned with systems that have many degrees of freedom (composite systems), are spatially extended (systems with both spatial and temporal degrees of freedom), and are dissipative as well as nonlinear due to the rich interactions among the local components (agents). Some of the terms associated with such systems are emergent global behavior, collective behavior, cooperative behavior, self-organization, critical phenomena, and scale invariance.
- Criticality:** A state of a system where spatial and/or temporal characteristics are scale invariant.
- Emergent global behavior:** The observable behavior of a system that cannot be deduced from the properties of constituent components considered in isolation and results from the collective (cooperative or competitive) evolution of local events.
- Fractal:** Refers to physical objects or dynamic processes that reveal new details on space or time magnification. Fractals lack a characteristic scale.
- Fractional brownian motion:** A generalization of the random function created by the record of the motion of a "brownian particle" executing random walk. Brownian motion is commonly used to model diffusion in constraint-free media. Fractional brownian motion is often used to model diffusion of particles in constrained environments or anomalous diffusion.
- Percolation:** A simple mathematical construct commonly used to measure the extent of connectedness in a partially occupied (site percolation) or connected (bond percolation) lattice structure.
- Phase transition:** Any abrupt change between the physical and/or the dynamic states of a system, usually between ordered and disordered organization or behavior.
- Renormalization:** Changing the characteristic scale of a measurement through a process of systematic averaging applied to the microscopic elements of a system (also referred to as coarse graining).
- Scaling:** Structures or dynamics that maintain some form of exact or statistical invariance under transformations of scale.
- Self-organization:** The spontaneous emergence of order. This occurs without the direction of a global controller.
- Self-similarity:** A subset of objects and processes in the scaling category that remain invariant under ordinary geometric similarity.

The long anticipated “information age” is taking shape at the cross-section of **multimedia** signal processing and telecommunications-based networking. By defying the traditional concepts of space and time, these emerging technologies promise to affect all facets of our lives in a pervasive and profound manner [Mayo, 1992]. The physical constraints of location have naturally led, over the centuries, to the creation of the conventional patient care services and facilities. As the “information superhighway” is laid down with branches spanning the nation, and eventually the world via wired and wireless communication channels, we will come closer to a bold new era in health care delivery, namely, the era of remote monitoring, diagnosis, and intervention.

Forward-looking medical industries are engaging in research and development efforts to capitalize on the emerging technologies. Medical institutions in particular recognize the transforming power of the impending revolution. A number of hospitals are undertaking pilot projects to experiment with the potentials of the new communication and interaction media that will constitute the foundations of futuristic health care systems. There is consensus among health care administrators that the agility and

effectiveness with which an institution positions itself to fully embrace the new medical lifestyle will decide its viability in the next millennium.

Although multimedia communications is yet in its infancy, recent developments foretell a bright future. Many agree that multimedia networking is becoming a reality thanks to advances in digital signal-processing research and development. Trends toward implementation of algorithms by fewer components are leading to decreasing hardware complexity while increasing processing functionality [Andrews, 1994]. The vast and vibrant industry producing multimedia hardware and software ranging from application-specific digital signal processors and video chip sets to videophones and multimedia terminals heavily relies on digital signal processing know-how.

As in the case of generic digital signal processing, biomedical signal processing is expected to play a key role in mainstreaming patient care at a distance. Earlier in this section, emerging methods in biomedical signal analysis that promise major enhancements in our ability to extract information from vital signals were introduced. This chapter provides a glimpse of the future — when biomedical signals will be integrated with other patient information and transmitted via networked multimedia — by examining trends in key communications technologies, namely, public switched-network protocols, wireless communications, **photonics**, and **virtual reality**.

## 9.1 Public Switched Network and Asynchronous Transfer Mode

---

The public switched network already can accommodate a wide array of networked multimedia communications. The introduction of new standards such as the **asynchronous transfer mode (ATM)** is a strong sign that the network will evolve to handle an array of novel communication services.

ATM is a technology based on a switched network that uses dedicated media connections [ATM Networking, 1994]. Each connection between users is physically established by setting up a path or virtual channel through a series of integrated circuits in the switch. In conventional shared media networks, connections are made by breaking the information into packets labeled with their destination; these packets then share bandwidth until they reach their destination. In switched networks, instead of sharing bandwidth, connections can be run in parallel, since each connection has its own pathway. This approach prevents degradation of the response time despite an increased number of users who are running intensive applications on the network, such as videoconferencing. Therefore, ATM offers consistently high performance to all users on the network, particularly in real-time networked multimedia applications which often encounter severe response time degradation on shared media networks. Also, the ATM standards for both local area networks (LANs) and wide area networks (WANs) are the same; this allows for seamless integration of LANs and WANs.

Small-scale experiments based on ATM-based multimedia communications have already been launched in a number of medical centers. Early examples involve departments where doctors and staff can remotely work on chest x-rays, **CT** exams, and **MRI** images around the hospital over an ATM switched network. Since ATM integrates LANs and WANs, collaborating institutions will be able to access the same information in the future. Similar patient multimedia information-sharing efforts are underway which integrate all vital information including physiologic signals and sounds, images, and video and patient data and make them available remotely. In some recent experiments, the access is accomplished in real time such that medical conferencing, and hence remote diagnosis, becomes a possibility.

## 9.2 Wireless Communication

---

Wireless communication is the fastest growing sector of the telecommunications industry [Wittman, 1994]. **Wireless networking** technology is rapidly coming of age with the recent passage of initial standards, widespread performance improvements, and the introduction of personal communications networks (PCNs). Pocket-sized portable “smart” terminals are combined with wireless communication to free users

from the constraints of wired connection to networks. The progress in this direction is closely monitored by the health care community because the technology holds the potential to liberate ambulatory patients who require long-term monitoring and processing of biomedical signals for timely intervention. Wireless and interactive access by medical personnel to physiologic multimedia information will no doubt be a staple of the future distributed health care delivery systems.

## 9.3 Photonics

---

Photonics, or lightwave, is an evolving technology with the capacity to support a wide range of high-bandwidth multimedia applications. In current practice, photonics plays a complementary role to electronics in the hybrid technology referred to as electro-optics. Optical fibers are widely used for transmission of signals, from long-distance links to undersea cables to local loops linking customers with the central switching office. The trend in photonics is to move beyond functions limited to transmission toward logic operations. Recent advances in photonic logic devices suggest that optical computers may present characteristics more desirable than electronics in many biomedical processing applications requiring parallel tasks. A case in point is online pattern recognition, which may bring a new dimension to remote diagnosis.

## 9.4 Virtual Reality

---

Virtual reality — the ultimate networked multimedia service — is a simulated environment that enables one to remotely experience an event or a place in all dimensions. Virtual reality makes telepresence possible. The nascent technology builds on the capabilities of interactive telecommunications and is expected to become a consumer reality early in the next century. Applications in the field of endoscopic surgery are being developed. Demonstration projects in remote surgery are underway, paving the way for remote medical intervention.

## Acknowledgment

Contributions by Prabhakar R. Chitrapu, Dialogic Corporation, to material on networked multimedia communications in this chapter are gratefully acknowledged.

## Defining Terms

**ATM (asynchronous transfer mode):** Technology based on a switched network that uses dedicated media connections.

**CT:** Computer tomography.

**MRI:** Magnetic resonance imaging.

**Multimedia:** Technology to integrate sights, sounds, and data. The media may include audio signals such as speech, music, biomedical sounds, images, animation, and video signals, as well as text, graphics, and fax. One key feature is the common linkage, synchronization, and control of the various media that contribute to the overall multimedia signal. In general, multimedia services and products are interactive, hence real-time, as in the case of collaborative computing and videoconferencing.

**Photonics:** Switching, computing, and communications technologies based on lightwave.

**Virtual reality:** Technology that creates a simulated environment enabling one to remotely experience an event or a place in all dimensions.

**Wireless network:** Technology based on communication between nodes such as stationary desktops, laptops, or personal digital assistants (PDAs) and the LAN hub or access point using a wireless adapter with radio circuitry and an antenna. The LAN hub has a LAN attachment on one interface and one or more antennas on another.

**I**MAGING HAS BECOME AN INTEGRAL PART of medical care. The ability to obtain information about the anatomic and physiologic status of the body without the need for direct visualization has dramatically altered the practice of medicine.

X-rays provided the first technical capability to image inside the body. X-rays provide a two-dimensional image of a three-dimensional space. Their contrast mechanism is primarily dependent upon the absorption of high-energy photons by water and calcium salts within the body. X-rays are therefore very effective at imaging bony structures but less sensitive to soft tissue defects. The use of contrast materials based on x-ray absorbing substances such as barium and iodine allow visualization of the gastrointestinal tract, urinary tract, and cardiovascular system. X-ray techniques initially required a large x-ray generator and a film holder to obtain an image. More recently all-digital systems have been introduced reducing or eliminating the need for film.

Digital mammography has found widespread acceptance. Detectors used in digital mammography demonstrate significantly improved detective quantum efficiency curves compared with screen film mammography systems [1]. This improves the ability to detect fine, low-contrast detail at the same radiation dose or reduced dose to maintain the same level of image quality. A variety of digital mammography systems based on charge-couple devices, amorphous silicon technology, and amorphous selenium technology are on the market. Digital systems allow optimization of each stage in the imaging chain. Further image improvement is achieved through image processing techniques and the use of high-resolution displays. New imaging reconstruction techniques are currently being explored. However, x-ray imaging still requires the patient, the clinician, and the technicians to be exposed to radiation. The need for shielding and the desire for continuous imaging without the need for radiation stimulated the search for alternative imaging techniques.

Optical imaging techniques beyond direct physical observation were made feasible by the development of fiber optics and optical relay systems. Endoscopy, the use of optical imaging systems to look inside the body, makes use of the body's channels to gain access to hollow organs. Laparoscopy, arthroscopy, thoracoscopy, and other similar techniques distend potential spaces within the body, such as the abdominal cavity, joint cavities, and pleural spaces, to allow placement of a rigid telescope that brings light into the space and relays images out to the clinician. The development of small TV cameras which could be attached directly to the endoscope eliminated the need for the clinician to have his/her eye at the end of the endoscope. The creation of video endoscopy greatly facilitated the use of endoscopic techniques for both diagnostic and therapeutic purposes. As the endoscopes became more sophisticated the ability to guide procedures with these devices grew rapidly. In 1987 there were no laparoscopic cholecystectomies in the United States. The technique, which uses a rigid endoscope and a series of tools to operate within the peritoneal cavity, permits minimally invasive surgical removal of the gallbladder. By 1995 more than 550,000 laparoscopic cholecystectomies were performed yearly in the United States. Hospital stay decreased from 5–7 days to 1–2 days per patient with a concomitant reduction in need for pain medication and a dramatic decrease in overall costs of the procedure.

Flexible endoscopy has had a similar impact on the diagnosis and treatment of colonic polyps, esophageal stricture, and pulmonary biopsy procedures. Rigid endoscopy has been effectively applied to orthopedics, where it is used to inspect large and small joints and permits surgeons to perform repairs without opening the joint. As with other imaging modalities, the ability to observe and define pathology becomes the basis for the development of new therapeutic techniques. More than 10 million endoscopic procedures are performed annually in the United States. Optical techniques cannot see inside solid organs, and the ability to apply optical imaging is limited to those procedures that can be accomplished under direct visualization.

Ultrasound technologies can generate images of solid organs with mobile systems that do not require exposure to radiation. Ultrasound is particularly effective at imaging the heart, kidneys, liver, and other solid organs. Unfortunately, ultrasound does not effectively penetrate bone or air–water interfaces. Therefore imaging of the brain and lungs is rarely possible with ultrasonic techniques. Ultrasound can provide

information on the flow of blood through arteries and veins, and Doppler techniques can identify the direction of flow. Fetal ultrasound is responsible for dramatic advances in the development of neonatal medicine and the treatment of congenital defects in utero. Recent developments in ultrasonic imaging include dramatic reductions in the size of the instruments, the ability to generate three-dimensional data sets, and the use of ultrasound to guide procedures such as breast and liver biopsies. As techniques have improved sensitivity has increased, and the ability to identify and localize pathologic tissue has increased. The development of all these techniques has, in general, shortened hospital stay and allowed for earlier and more accurate diagnosis of disease and development of more effective treatment plans.

Naqvi reported extensive use of three-dimensional ultrasound for cardiac procedures [2]. This technology provides the clinician with an effective presentation of cardiac structure, which allows bedside diagnosis. Echocardiography is the predominant imaging modality for assessing patients with congenital heart disease [3]. It is simple to use, provides high-resolution images with real-time feedback, and now allows characterization of myocardial strain rate. These data provide the clinician with a clear indication of cardiac function. Ultrasonography also provides precise anatomic information in the study of vascular occlusive disease, particularly in the analysis of carotid stenosis [4]. The development of contrast media for ultrasound is improving the ability of ultrasound to identify specific tissues and localize organs [5]. Miniaturized ultrasound transducers have extended high-resolution ultrasonic imaging to the vascular tree and the digestive tract. These new imaging formats provide a wealth of three-dimensional data on the structure of these anatomic systems.

Computed tomography (CT) scanning provided the first high-resolution, three-dimensional imaging capability. Two-dimensional slices were obtained and reassembled to form a three-dimensional reconstruction of solid organs. In the 1970s true three-dimensional images obtained in live patients became a reality. Over the last 35 years CT scanning has evolved and now employs helical and electron beam technologies to produce faster, more accurate scans. Advances in CT computer programs permit virtual endoscopic representations of the gastrointestinal tract, pulmonary tree, and cardiovascular tree. The ability to perform organ segmentation and generate three-dimensional reconstructions from two-dimensional slices is driving the development of both CT and MR colonography and CT bronchography, cystography, and arthrography. The American Gastroenterological Association studied the current status of CT colonography [6]. They concluded that it was an attractive imaging modality with a significant potential impact on the practice of gastroenterology. The report details the broad variability seen in the literature on the current effectiveness of this technology. Cotton et al. [7] concluded that the technology held promise but was not yet ready for widespread clinical application. As the technology improves these imaging technologies are likely to alter the current practice of medicine.

As the ability to image anatomic structures improved, clinicians desired techniques to monitor function of specific organs. Radiopharmaceuticals provided a means of obtaining images that were based on the physiologic function of an organ. The ability to define the functional status of multiple organs including the heart, the liver, the kidneys, the gallbladder, etc. allowed clinicians to correlate physiology with disease states. As radiopharmaceutical chemistry improved, the ability to make imaging agents for specific organs required the development of unique radionuclides. When linked to the right carrier molecule, radionuclides provide imaging agents for cardiac ischemia, breast cancer imaging, kidney function, and prostate cancer imaging. The principal limitation of these techniques is the inability to precisely define the location of the problem in a three-dimensional system.

Positron emission tomography (PET) was developed in part to address the limitations of standard radionuclide imaging. As detailed in the chapter by Budinger and VanBrocklin, PET scanning can generate two-dimensional images from a one-dimensional projection seen at different angles. These two-dimensional constructs can be assembled into a three-dimensional map.

The successes of x-ray, ultrasound, and radionuclide imaging demonstrated the value of these techniques in patient care, but the limitations of these techniques stimulated scientists to explore new methods of imaging. Magnetic resonance imaging (MRI) uses radiofrequency energy and oscillating electromagnetic fields to determine the chemical structure of materials within a magnetic field. This information

is then processed to generate a three-dimensional reconstruction based on the signals obtained from excitation of the hydrogen nuclei, as detailed in Chapter 63. Like x-ray systems, MRI can be enhanced by the use of unique dyes. Under the proper conditions MRI imaging can give true three-dimensional data regarding a particular area within the body or provide data on the functional status of a particular tissue.

Functional magnetic resonance imaging (fMRI) uses blood oxygenation levels as a contrast medium. This technique has been applied to investigation of the brain. Recent studies have expanded the use of bold fMRI with the use of high-field (3.0 T or greater) magnets [8]. High-field magnetic resonance spectroscopy allows greater accuracy in quantitative measurements and decrease in voxel size. Improvements in MR spectroscopy improve our understanding of the organization of the brain. Diffusion tensor imaging allows MR imaging of actual fiber tracts within the brain. At high-field strength DTI techniques reveal the complexity of neuronal interconnections [9]. High-field MRI is gaining acceptance across a broad range of applications. Investigations have noted some unpleasant transient phenomena but no long-term sequelae from these intense magnetic fields. The increases in signal-to-noise lead to dramatic improvements in image quality. MRI angiography improves as vessels appear brighter and smaller vessels become visible. At 3 T the combination of improved background suppression and increased signal-to-noise extends the capability of MRA to the smaller vessels. Orthopedic and cardiac imaging are significantly improved as well. In higher magnetic fields it is possible to use phosphorus, carbon, sodium, and fluorine as the basis for imaging. Studies exploring the use of these nuclei are now feasible at higher fields [10].

Cardiac MRI is rapidly becoming the imaging modality of choice for studying cardiac structure, function, perfusion, and viability at the same time. In many situations it is superior to other modalities. Cardiac magnetic resonance has been applied to the diagnosis of aortic aneurismal disease, valvular heart disease, congenital heart disease, and ischemic heart disease. Cardiac MRI perfusion techniques are now competing with nuclear medicine techniques. Comprehensive assessment of the coronary arteries and functional status of the underlying ventricle has been shown to be feasible but is not yet routinely performed. Interventional techniques based on magnetic resonance fluoroscopy are of great interest to the cardiovascular community, but several significant hurdles, including the cost of the instrumentation, the need for nonmagnetic guidewires and stents, and the difficulty in defining small vessels, are only now being addressed [11].

Positron emission tomography (PET) allows for collection of functionally based images using 18F-FDG as a radiotracer. 18F-FDG permits detection of small tumors but is difficult to precisely locate. The challenge has been to fuse imaging techniques while retaining the advantages of each modality. PET scans are now routinely combined with CT scans. Recent articles by Goerres [12], Townsend [13], Gaa [14], Buscombe [15], Wahl [16], and Kim [17] demonstrate the trend of combining PET with CT or MRI. In each of these papers PET identifies an area of potential malignancy and the CT or MRI scan provides the anatomic details. Registration algorithms allow for precise localization of the PET data into the three-dimensional anatomic image constructed from the CT or MR data. PET/CT and PET/MRI improves the diagnostic accuracy compared to PET alone. The ability to integrate information is becoming critical to the patient care process [5]. Images are now moved through picture archiving and communications systems (PACS) via networks and work stations. The availability of fused data allows for greater precision in planning surgical procedures and radiation therapy.

Advances in digital or filmless systems and the use of flat panel displays has changed the design and improved the flexibility of the radiology suite. As digital radiography becomes more prominent archiving the information in digital form will become more commonplace. Systems that allow for long-range consulting, teleradiology, are being developed. Thus an individual with great skill, such as a pediatric orthopedic radiologist, can receive information from hundreds to thousands of miles away, interpret an image, and provide feedback to an emergency room physician.

The following chapters provide a concise review of the techniques, instrumentation, and applications involved in imaging systems: Chapter 10: x-ray equipment; Chapter 11: computed tomography (CT); Chapter 12: magnetic resonance imaging (MRI); Chapter 13: nuclear medicine; Chapter 14: ultrasound techniques; Chapter 15: magnetic resonance microscopy (MRM); Chapter 16: positron emission tomography (PET); Chapter 17: electrical impedance tomography (EIT).

Chapter 18 discusses medical applications of virtual reality (VR) technology, an area that is taking advantage of rapid advances in computer processing power and improved display techniques. VR applications including virtual colonoscopy, preoperative planning, surgical simulations, and training systems are the subject of detailed investigation to identify their role in healthcare. While still in their infancy these technologies will drive development of less invasive technologies and improve the outcome of surgical procedures.

### 10.1 X-Ray Equipment

---

*Robert E. Shroy, Jr.*

Conventional x-ray radiography produces images of anatomy that are shadowgrams based on x-ray absorption. The x-rays are produced in a region that is nearly a point source and then are directed on the anatomy to be imaged. The x-rays emerging from the anatomy are detected to form a two-dimensional image, where each point in the image has a brightness related to the intensity of the x-rays at that point. Image production relies on the fact that significant numbers of x-rays penetrate through the anatomy and that different parts of the anatomy absorb different amounts of x-rays. In cases where the anatomy of interest does not absorb x-rays differently from surrounding regions, contrast may be increased by introducing strong x-ray absorbers. For example, barium is often used to image the gastrointestinal tract.

X-rays are electromagnetic waves (like light) having an energy in the general range of approximately one to several hundred kiloelectronvolts (**keV**). In medical x-ray imaging, the x-ray energy typically lies between 5 and 150 keV, with the energy adjusted to the anatomic thickness and the type of study being performed.

X-rays striking an object may either pass through unaffected or may undergo an interaction. These interactions usually involve either the photoelectric effect (where the x-ray is absorbed) or scattering (where the x-ray is deflected to the side with a loss of some energy). X-rays that have been scattered may undergo deflection through a small angle and still reach the image detector; in this case they reduce image contrast and thus degrade the image. This degradation can be reduced by the use of an air gap between the anatomy and the image receptor or by use of an **antiscatter grid**.

Because of health effects, the doses in radiography are kept as low as possible. However, x-ray quantum noise becomes more apparent in the image as the dose is lowered. This noise is due to the fact that there is an unavoidable random variation in the number of x-rays reaching a point on an image detector. The quantum noise depends on the average number of x-rays striking the image detector and is a fundamental limit to radiographic image quality.

The equipment of conventional x-ray radiography mostly deals with the creation of a desirable beam of x-rays and with the detection of a high-quality image of the transmitted x-rays. These are discussed in the following sections.

## 10.1.1 Production of X-Rays

### 10.1.1.1 X-Ray Tube

The standard device for production of x-rays is the rotating anode x-ray tube, as illustrated in Figure 10.1. The x-rays are produced from electrons that have been accelerated in vacuum from the cathode to the anode. The electrons are emitted from a filament mounted within a groove in the cathode. Emission occurs when the filament is heated by passing a current through it. When the filament is hot enough, some electrons obtain a thermal energy sufficient to overcome the energy binding the electron to the metal of the filament. Once the electrons have “boiled off” from the filament, they are accelerated by a voltage difference applied from the cathode to the anode. This voltage is supplied by a generator (see Section 10.1.1.2).

After the electrons have been accelerated to the anode, they will be stopped in a short distance. Most of the electrons’ energy is converted into heating of the anode, but a small percentage is converted to x-rays by two main methods. One method of x-ray production relies on the fact that deceleration of a charged particle results in emission of electromagnetic radiation, called bremsstrahlung radiation. These x-rays will have a wide, continuous distribution of energies, with the maximum being the total energy

FIGURE 10.1 X-ray tube.

the electron had when reaching the anode. The number of x-rays is relatively small at higher energies and increases for lower energies.

A second method of x-ray production occurs when an accelerated electron strikes an atom in the anode and removes an inner electron from this atom. The vacant electron orbital will be filled by a neighboring electron, and an x-ray may be emitted whose energy matches the energy change of the electron. The result is production of large numbers of x-rays at a few discrete energies. Since the energy of these characteristic x-rays depends on the material on the surface of the anode, materials are chosen partially to produce x-rays with desired energies. For example, molybdenum is frequently used in anodes of mammography x-ray tubes because of its 20-keV characteristic x-rays.

Low-energy x-rays are undesirable because they increase dose to the patient but do not contribute to the final image because they are almost totally absorbed. Therefore, the number of low-energy x-rays is usually reduced by use of a layer of absorber that preferentially absorbs them. The extent to which low-energy x-rays have been removed can be quantified by the **half-value layer** of the x-ray beam.

It is ideal to create x-rays from a point source because any increase in source size will result in blurring of the final image. Quantitatively, the effects of the blurring are described by the **focal spot's** contribution to the system **modulation transfer function (MTF)**. The blurring has its main effect on edges and small objects, which correspond to the higher frequencies. The effect of this blurring depends on the geometry of the imaging and is worse for larger distances between the object and the image receptor (which corresponds to larger geometric magnifications).

To avoid this blurring, the electrons must be focused to strike a small spot of the anode. The focusing is achieved by electric fields determined by the exact shape of the cathode. However, there is a limit to the size of this focal spot because the anode material will melt if too much power is deposited into too small an area. This limit is improved by use of a rotating anode, where the anode target material is rotated about a central axis and new (cooler) anode material is constantly being rotated into place at the focal spot. To further increase the power limit, the anode is made with an angle surface. This allows the heat to be deposited in a relatively large spot while the apparent spot size at the detector will be smaller by a factor of the sine of the anode angle. Unfortunately, this angle cannot be made too small because it limits the area that can be covered with x-rays. In practice, tubes are usually supplied with two (or more) focal spots of differing sizes, allowing choice of a smaller (sharper, lower-power) spot or a larger (more blurry, higher-power) spot.

The x-ray tube also limits the total number of x-rays that can be used in an exposure because the anode will melt if too much total energy is deposited in it. This limit can be increased by using a more massive anode.

### 10.1.1.2 Generator

The voltages and currents in an x-ray tube are supplied by an x-ray generator. This controls the cathode-anode voltage, which partially defines the number of x-rays made because the number of x-rays produced increases with voltage. The voltage is also chosen to produce x-rays with desired energies: higher voltages makes x-rays that generally are more penetrating but give a lower contrast image. The generator also determines the number of x-rays created by controlling the amount of current flowing from the cathode to anode and by controlling the length of time this current flows. This points out the two major parameters that describe an x-ray exposure: the peak kilovolts (peak kilovolts from the anode to the cathode during the exposure) and the milliamperere-seconds (the product of the current in milliamperes and the exposure time in seconds).

The peak kilovolts and milliamperere-seconds for an exposure may be set manually by an operator based on estimates of the anatomy. Some generators use manual entry of kilovolts and milliamperes but determine the exposure time automatically. This involves sampling the radiation either before or after the image sensor and is referred to as phototiming.

The anode-cathode voltage (often 15 to 150 kV) can be produced by a transformer that converts 120 or 220 V ac to higher voltages. This output is then rectified and filtered. Use of three-phase transformers gives voltages that are nearly constant versus those from single-phase transformers, thus avoiding low

kilovoltages that produce undesired low-energy x-rays. In a variation of this method, the transformer output can be controlled at a constant voltage by electron tubes. This gives practically constant voltages and, further, allows the voltage to be turned on and off so quickly that millisecond exposure times can be achieved. In a third approach, an ac input can be rectified and filtered to produce a nearly dc voltage, which is then sent to a solid-state inverter that can turn on and off thousands of times a second. This higher-frequency ac voltage can be converted more easily to a high voltage by a transformer. Equipment operating on this principle is referred to as midfrequency or high-frequency generators.

### 10.1.2 Image Detection: Screen Film Combinations

Special properties are needed for image detection in radiographic applications, where a few high-quality images are made in a study. Because decisions are not immediately made from the images, it is not necessary to display them instantly (although it may be desirable).

The most commonly used method of detecting such a radiographic x-ray image uses light-sensitive negative film as a medium. Because high-quality film has a poor response to x-rays, it must be used together with x-ray-sensitive screens. Such screens are usually made with  $\text{CaWO}_2$  or phosphors using rare earth elements such as doped  $\text{Gd}_2\text{O}_2\text{S}$  or  $\text{LaOBr}$ . The film is enclosed in a light-tight cassette in contact with an x-ray screen or in between two x-ray screens. When a x-ray image strikes the cassette, the x-rays are absorbed by the screens with high efficiency, and their energy is converted to visible light. The light then exposes a negative image on the film, which is in close contact with the screen.

Several properties have been found to be important in describing the relative performance of different films. One critical property is the contrast, which describes the amount of additional darkening caused by an additional amount of light when working near the center of a film's exposure range. Another property, the latitude of a film, describes the film's ability to create a usable image with a wide range in input light levels. Generally, latitude and contrast are competing properties, and a film with a large latitude will have a low contrast. Additionally, the modulation transfer function (MTF) of a film is an important property. MTF is most degraded at higher frequencies; this high-frequency MTF is also described by the film's resolution, its ability to image small objects.

X-ray screens also have several key performance parameters. It is essential that screens detect and use a large percentage of the x-rays striking them, which is measured as the screen's **quantum detection efficiency**. Currently used screens may detect 30% of x-rays for images at higher peak kilovolts and as much 60% for lower peak kilovolt images. Such efficiencies lead to the use of two screens (one on each side of the film) for improved x-ray utilization. As with films, a good high-frequency MTF is needed to give good visibility of small structures and edges. Some MTF degradation is associated with blurring that occurs when light spreads as it travels through the screen and to the film. This leads to a compromise on thickness; screens must be thick enough for good quantum detection efficiency but thin enough to avoid excess blurring.

For a film/screen system, a certain amount of radiation will be required to produce a usable amount of film darkening. The ability of the film/screen system to make an image with a small amount of radiation is referred to as its speed. The speed depends on a number of parameters: the quantum detection efficiency of the screen, the efficiency with which the screen converts x-ray energy to light, the match between the color emitted by the screen and the colors to which the film is sensitive, and the amount of film darkening for a given amount of light. The number of x-rays used in producing a radiographic image will be chosen to give a viewable amount of exposure to the film. Therefore, patient dose will be reduced by the use of a high-speed screen/film system. However, high-speed film/screen combinations gives a "noisier" image because of the smaller number of x-rays detected in its creation.

### 10.1.3 Image Detection: X-Ray Image Intensifiers with Televisions

Although screen-film systems are excellent for radiography, they are not usable for fluoroscopy, where lower x-ray levels are produced continuously and many images must be presented almost immediately.

FIGURE 10.2 X-ray image intensifier.

Fluoroscopic images are not used for diagnosis but rather as an aid in performing tasks such as placement of catheters in blood vessels during angiography. For fluoroscopy, x-ray image intensifiers are used in conjunction with television cameras. An x-ray image intensifier detects the x-ray image and converts it to a small, bright image of visible light. This visible image is then transferred by lenses to a television camera for final display on a monitor.

The basic structure of an x-ray image intensifier is shown in Figure 10.2. The components are held in a vacuum by an enclosure made of glass and/or metal. The x-rays enter through a low-absorption window and then strike an input phosphor usually made of doped Cesium iodide (CsI). As in the x-ray screens described above, the x-rays are converted to light in the CsI. On top of the CsI layer is a photoemitter, which absorbs the light and emits a number of low-energy electrons that initially spread in various directions. The photoelectrons are accelerated and steered by a set of grids that have voltages applied to them. The electrons strike an output phosphor structure that converts their energy to the final output image made of light. This light then travels through an output window to a lens system. The grid voltages serve to add energy to the electrons so that the output image is brighter. Grid voltages and shapes are also chosen so that the x-ray image is converted to a light image with minimal distortion. Further, the grids must be designed to take photoelectrons that are spreading from a point on the photoemitter and focus them back together at a point on the output phosphor.

It is possible to adjust grid voltages on an image intensifier so that it has different fields of coverage. Either the whole input area can be imaged on the output phosphor, or smaller parts of the input can be imaged on the whole output. Use of smaller parts of the input is advantageous when only smaller parts of anatomy need to be imaged with maximum resolution and a large display. For example, an image intensifier that could cover a 12-in.-diameter input also might be operated so that a 9-in.-diameter or 6-in.-diameter input covers all the output phosphor.

X-ray image intensifiers can be described by a set of performance parameters not unlike those of screen/film combinations. It is important that x-rays be detected and used with a high efficiency; current image intensifiers have quantum detection efficiencies of 60 to 70% for 59-keV x-rays. As with film/screens, a good high-frequency MTF is needed to image small objects and sharp edges without blurring. However,

low-frequency MTF also must be controlled carefully in image intensifiers, since it can be degraded by internal scattering of x-rays, photoelectrons, and light over relatively large distances. The amount of intensification depends on brightness and size of the output image for a given x-ray input. This is described either by the gain (specified relative to a standard x-ray screen) or by conversion efficiency (a light output per radiation input measured in  $(\text{cd}/\text{m}^2)/(\text{mR}/\text{min})$ ). Note that producing a smaller output image is as important as making a light image with more photons because the small image can be handled more efficiently by the lenses that follow. Especially when imaging the full input area, image intensifiers introduce a pincushion distortion into the output image. Thus a square object placed off-center will produce an image that is stretched in the direction away from the center.

Although an image intensifier output could be viewed directly with a lens system, there is more flexibility when the image intensifier is viewed with a television camera and the output is displayed on a monitor. Televisions are currently used with pickup tubes and with CCD sensors.

When a television tube is used, the image is focused on a charged photoconducting material at the tube's input. A number of materials are used, including  $\text{SbS}_3$ ,  $\text{PbO}$ , and  $\text{SeTeAs}$ . The light image discharges regions of the photoconductor, converting the image to a charge distribution on the back of the photoconducting layer. Next, the charge distribution is read by scanning a small beam of electrons across the surface, which recharges the photoconductor. The recharging current is proportional to the light intensity at the point being scanned; this current is amplified and then used to produce an image on a monitor. The tube target is generally scanned in an interlaced mode in order to be consistent with broadcast television and allow use of standard equipment.

In fluoroscopy, it is desirable to use the same detected dose for all studies so that the image noise is approximately constant. This is usually achieved by monitoring the image brightness in a central part of the image intensifier's output, since brightness generally increases with dose. The brightness may be monitored by a photomultiplier tube that samples it directly or by analyzing signal levels in the television. However, maintaining a constant detected dose would lead to high patient doses in the case of very absorptive anatomy. To avoid problems here, systems are generally required by federal regulations to have a limit on the maximum patient dose. In those cases where the dose limit prevents the image intensifier from receiving the usual dose, the output image becomes darker. To compensate for this, television systems are often operated with automatic gain control that gives an image on the monitor of a constant brightness no matter what the brightness from the image intensifier.

### 10.1.4 Image Detection: Digital Systems

In both radiography and fluoroscopy, there are advantages to the use of digital images. This allows image processing for better displayed images, use of lower doses in some cases, and opens the possibility for digital storage with a PACS system or remote image viewing via teleradiology. Additionally, some digital systems provide better image quality because of fewer processing steps, lack of distortion, or improved uniformity.

A common method of digitizing medical x-ray images uses the voltage output from an image-intensifier/TV system. This voltage can be digitized by an analog-to-digital converter at rates fast enough to be used with fluoroscopy as well as radiography.

Another technology for obtaining digital radiographs involves use of photostimulable phosphors. Here the x-rays strike an enclosed sheet of phosphor that stores the x-ray energy. This phosphor can then be taken to a read-out unit, where the phosphor surface is scanned by a small light beam of proper wavelength. As a point on the surface is read, the stored energy is emitted as visible light, which is then detected, amplified, and digitized. Such systems have the advantage that they can be used with existing systems designed for screen-film detection because the phosphor sheet package is the same size as that for screen films.

A new method for digital detection involves use of active-matrix thin-film-transistor technology, in which an array of small sensors is grown in hydrogenated amorphous silicon. Each sensor element includes an electrode for storing charge that is proportional to its x-ray signal. Each electrode is coupled to

a transistor that either isolates it during acquisition or couples it to digitization circuitry during read-out. There are two common methods for introducing the charge signal on each electrode. In one method, a layer of x-ray absorber (typically selenium) is deposited on the array of sensors; when this layer is biased and x-rays are absorbed there, their energy is converted to electron-hole pairs and the resulting charge is collected on the electrode. In the second method, each electrode is part of the photodiode that makes electron-hole pairs when exposed to light; the light is produced from x-rays by a layer of scintillator (such as CsI) that is deposited on the array.

Use of a digital system provides several advantages in fluoroscopy. The digital image can be processed in real time with edge enhancement, smoothing, or application of a median filter. Also, frame-to-frame averaging can be used to decrease image noise, at the expense of blurring the image of moving objects. Further, digital fluoroscopy with TV system allows the TV tube to be scanned in formats that are optimized for read-out; the image can still be shown in a different format that is optimized for display. Another advantage is that the displayed image is not allowed to go blank when x-ray exposure is ended, but a repeated display of the last image is shown. This last-image-hold significantly reduces doses in those cases where the radiologist needs to see an image for evaluation, but does not necessarily need a continuously updated image.

The processing of some digital systems also allows the use of pulsed fluoroscopy, where the x-rays are produced in a short, intense burst instead of continuously. In this method the pulses of x-rays are made either by biasing the x-ray tube filament or by quickly turning on and off the anode-cathode voltage. This has the advantage of making sharper images of objects that are moving. Often one x-ray pulse is produced for every display frame, but there is also the ability to obtain dose reduction by leaving the x-rays off for some frames. With such a reduced exposure rate, doses can be reduced by a factor of two or four by only making x-rays every second or fourth frame. For those frames with no x-ray pulse, the system repeats a display of the last frame with x-rays.

## Defining Terms

- Antiscatter grid:** A thin structure made of alternating strips of lead and material transmissive to x-rays. Strips are oriented so that most scattered x-rays go through lead sections and are preferentially absorbed, while unscattered x-rays go through transmissive sections.
- Focal spot:** The small area on the anode of an x-ray tube from where x-rays are emitted. It is the place where the accelerated electron beam is focused.
- Half-value layer (HVL):** The thickness of a material (often aluminum) needed to absorb half the x-ray in a beam.
- keV:** A unit of energy useful with x-rays. It is equal to the energy supplied to an electron when accelerated through 1 kV.
- Modulation transfer function (MTF):** The ratio of the contrast in the output image of a system to the contrast in the object, specified for sine waves of various frequencies. Describes blurring (loss of contrast) in an imaging system for different-sized objects.
- Quantum detection efficiency:** The percentage of incident x-rays effectively used to create an image.

## Further Information

*Medical Physics* is a monthly scientific and informational journal published for the American Association of Physicists in Medicine. Papers here generally cover evaluation of existing medical equipment and development of new systems. For more information, contact the American Association of Physicists in Medicine, One Physics Ellipse, College Park, MD 20740-3846.

The Society of Photo-Optical Instrumentation Engineers (SPIE) sponsors numerous conferences and publishes their proceedings. Especially relevant is the *annual conference on Medical Imaging*. Contact SPIE, P.O. Box 10, Bellham, WA 98277-0010.

Several corporations active in medical imaging work together under the National Electrical Manufacturers Association to develop definitions and testing standards for equipment used in the field. Information can be obtained from NEMA, 2101 L Street, N.W., Washington, DC 20037.

Critical aspects of medical x-ray imaging are covered by rules of the Food and Drug Administration, part of the Department of Health and Human Services. These are listed in the *Code of Federal Regulations*, Title 21. Copies are for sale by the Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402.

## 10.2 X-Ray Projection Angiography

---

*Michael S. Van Lysel*

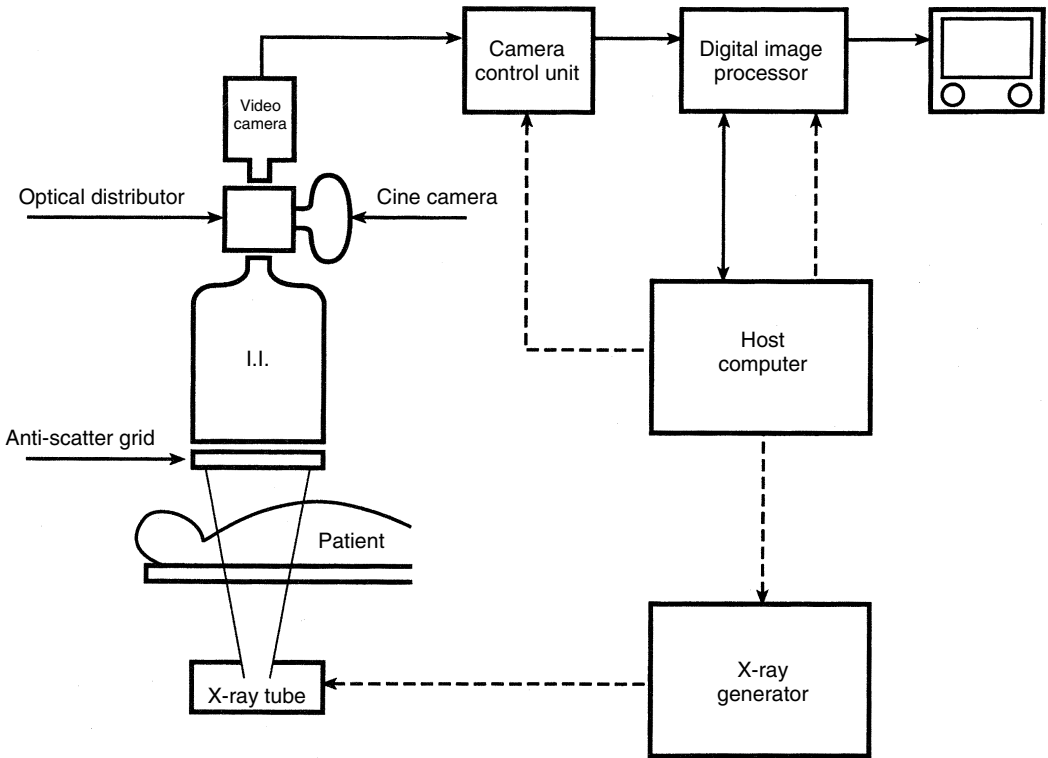

Angiography is a diagnostic and, increasingly, therapeutic modality concerned with diseases of the circulatory system. While many imaging modalities (ultrasound, computed tomography, magnetic resonance imaging, angiосcopy) are now available, either clinically or for research, to study vascular structures, this section will focus on projection radiography. In this method, the vessel of interest is opacified by injection of a radiopaque contrast agent. Serial radiographs of the contrast material flowing through the vessel are then acquired. This examination is performed in an angiographic suite, a special procedures laboratory, or a cardiac catheterization laboratory.

Contrast material is needed to opacify vascular structures because the radiographic contrast of blood is essentially the same as that of soft tissue. Contrast material consists of an iodine-containing ( $Z = 53$ ) compound, with maximum iodine concentrations of about 350 mg/cm<sup>3</sup>. Contrast material is injected through a catheter ranging in diameter roughly from 1 to 3 mm, depending on the injection flow rate to be used. Radiographic images of the contrast-filled vessels are recorded using either film or video.

Digital imaging technology has become instrumental in the acquisition and storage of angiographic images. The most important application of digital imaging is **digital subtraction angiography (DSA)**. **Temporal subtraction** is a DSA model in which a preinjection image (the mask) is acquired, the injection of contrast agent is then performed, and the sequential images of the opacified vessel(s) are acquired and subtracted from the mask. The result, ideally, is that the fixed anatomy is canceled, allowing contrast enhancement (similar to computed tomographic windowing and leveling) to provide increased contrast sensitivity.

An increasingly important facet of the angiographic procedure is the use of transluminal interventional techniques to effect a therapeutic result. These techniques, including angioplasty, atherectomy, laser ablation, and intraluminal stents, rely on digital angiographic imaging technology to facilitate the precise catheter manipulations necessary for a successful result. In fact, digital enhancement, storage, and retrieval of fluoroscopic images have become mandatory capabilities for digital angiographic systems.

Figure 10.3 is a schematic representation of an angiographic imaging system. The basic components include an x-ray tube and generator, image intensifier, video camera, cine camera (optional for cardiac imaging), and digital image processor.

**FIGURE 10.3** Schematic diagram of an image intensifier-based digital angiographic and cine imaging system. Solid arrows indicate image signals, and dotted arrows indicate control signals.

### 10.2.1 X-Ray Generation

Angiographic systems require a high-power, sophisticated x-ray generation system in order to produce the short, intense x-ray pulses needed to produce clear images of moving vessels. Required exposure times range from 100 to 200 msec for cerebral studies to 1 to 10 msec for cardiac studies. Angiographic systems use either a constant potential generator, or, increasingly, a medium/high-frequency inverter generator. Power ratings for angiographic generators are generally greater than or equal to 80 kW at 100 kV and must be capable of producing reasonably square x-ray pulses. In most cases (pediatric cardiology being an exception), pulse widths of 5 msec or greater are necessary to keep the x-ray tube potential in the desirable, high-contrast range of 70 to 90 kVp.

The x-ray tube is of the rotating-anode variety. Serial runs of high-intensity x-ray pulses result in high heat loads. Anode heat storage capacities of 1 mega-heat units (MHU) or greater are required, especially in the case of cine angiography. Electronic “heat computers,” which calculate and display the current heat load of the x-ray tube, are very useful in preventing damage to the x-ray tube. In a high-throughput angiographic suite, forced liquid cooling of the x-ray tube housing is essential. Angiographic x-ray tubes are of multifocal design, with the focal spot sizes tailored for the intended use. A 0.6-mm (50-kW loading), 1.2-mm (100-kW loading) bifocal insert is common. The specified heat loads for a given focal spot are for single exposures. When serial angiographic exposures are performed, the focal spot load limit must be derated (reduced) to account for the accumulation of heat in the focal spot target during the run. Larger focal spots (e.g., 1.8 mm) can be obtained for high-load procedures. A smaller focal spot (e.g., 0.3 and 0.1 mm [bias]) is needed for magnification studies. Small focal spots have become increasingly desirable for high-resolution fluoroscopic interventional studies performed with 1000-line video systems.

**FIGURE 10.4** Schematic diagram of the optical distributor used to couple the image intensifier (I.I.) output phosphor to a video and cine camera. (From Van Lysel, M.S. In S. Baum (ed.), *Abrams' Angiography*, 4th ed. Boston, Little, Brown. With permission.)

## 10.2.2 Image Formation

### 10.2.2.1 Film

From the 1950s to 1980s, the dominant detector system used for recording the angiographic procedure was film/screen angiography using a rapid film changer [Amplatz, 1997]. However, digital angiography, described below, has almost completely replaced this technology. Film provides a higher spatial resolution than digital. However, as the spatial resolution of digital continues to improve, the overwhelming advantages of ease of use and image processing algorithms have prevailed. While film changers can still be found in use, few new film/screen systems are being purchased.

One application where film use is still common is cardiac imaging. Cine angiography is performed with a 35-mm motion picture camera optically coupled to the image intensifier output phosphor (Figure 10.4). The primary clinical application is coronary angiography and ventriculography. During cine angiography, x-ray pulses are synchronized both with the cine camera shutter and the vertical retrace of the system video camera. To limit motion blurring, it is desirable to keep the x-ray pulses as short as possible, but no longer than 10 msec.

Imaging runs generally last from 5 to 10 sec in duration at a frame rate of 30 to 60 frames/sec (fps). Sixty fps is generally used for pediatric studies, where higher heart rates are encountered, while 30 fps is more typical for adult studies ("digital cine," discussed below, generally is performed at 15 fps). Some cine angiographic installations provide biplane imaging in which two independent imaging chains can acquire orthogonal images of the injection sequence. The eccentricity of coronary lesions and the asymmetric

nature of cardiac contraction abnormalities require that multiple x-ray projections be acquired. Biplane systems allow this to be done with a smaller patient contrast load. For this reason, biplane systems are considered a requirement for pediatric cath labs. They are relatively uncommon for adult cath labs, however, where the less complicated positioning of a single plane system is often valued over the reduced number of injections possible with a biplane system. The AP and lateral planes of a biplane system are energized out of phase, which results in the potential for image degradation due to detection of the radiation scattered from the opposite plane. Image intensifier blanking, which shuts down the accelerating voltage of the nonimaging plane, is used to eliminate this problem.

While film remains in common use for cardiac imaging, here too the medium is being replaced by digital. Digital angiographic systems (described below) were integrated into the cardiac catheterization imaging system beginning in the 1980s, to provide short term image storage and replay. However, the high resolution and frame rate required for cardiac imaging precluded the use of digital hardware for long-term (greater than one day) storage. Film and cine are acquired simultaneously using the beam splitting mirror in the optical distributor (Figure 10.4). This situation is rapidly changing, as high-speed video servers and the recordable compact disc (CD-R) now provide acceptable performance for this application. Most new cardiac imaging systems are purchased without a cine film camera.

#### 10.2.2.2 Image Intensifier/Video Camera

The image intensifier (II) is fundamental to the modern angiographic procedure. The purpose of the image intensifier is (1) to produce a light image with sufficient brightness to allow the use of video and film cameras and (2) to produce an output image of small enough size to allow convenient coupling to video and film cameras. The image intensifier provides both real-time imaging capability (fluoroscopy), which allows patient positioning and catheter manipulation, and recording of the angiographic injection (digital angiography, analog video recording, photospot, cine).

Image intensifier output phosphors are approximately 25 mm in diameter, although large (e.g., 50 to 60 mm) output phosphor image intensifiers have been developed to increase spatial resolution. The modulation transfer function (MTF) of the image intensifier is determined primarily by the input and output phosphor stages, so mapping a given input image to a larger output phosphor will improve the MTF of the system. The input phosphor of a modern image intensifier is cesium iodide (CsI). The largest currently available image intensifier input phosphors are approximately 16 in. The effective input phosphor diameter is selectable by the user. For example, an image intensifier designated 9/7/5 allows the user to select input phosphor diameters of 9, 7, or 5 in. These selections are referred to as image intensifier modes. The purpose of providing an adjustable input phosphor is to allow the user to trade off between spatial resolution and field of view. A smaller mode provides higher spatial resolution both because the MTF of the image intensifier improves and because it maps a smaller field of view to the fixed size of the video camera target. Generally speaking, angiographic suites designed exclusively for cardiac catheterization use 9-in. image intensifiers, neuroangiography suites use 12-in. intensifiers, while suites that must handle pulmonary, renal, or peripheral angiography require the larger (i.e., 14 to 16 in.) intensifiers.

The brightness gain of the image intensifier derives from two sources (1) the increase in electron energy produced by the accelerating potential (the flux gain) and (2) the decrease in size of the image as it is transferred from the input to the output phosphor (the minification gain). The product of these two factors can exceed 5000. However, since the minification gain is a function of the area of the input phosphor exposed to the radiation beam (i.e., the image intensifier mode), the brightness gain drops as smaller image intensifier modes are selected. This is compensated for by a combination of increasing x-ray exposure to maintain the image intensifier light output and opening the video camera aperture. Image intensifier brightness gain declines with age and must be monitored to allow timely replacement. The specification used for this purpose is the image intensifier conversion factor, defined as the light output of the image intensifier per unit x-ray exposure input. Modern image intensifiers have a conversion factor of 100  $\text{cd/m}^2/\text{mR/sec}$  or more for the 9-in. mode.

With the increasing emergence of digital angiography as the primary angiographic imaging modality, image intensifier performance has become increasingly important. In the field, the high-spatial-frequency of an image intensifier is assessed by determining the limiting resolution [in the neighborhood of 4 to 5 line-pairs/mm (lp/mm) in the 9-in. mode], while the low-spatial-frequency response is assessed using the contrast ratio (in the neighborhood of 15 : 1 to 30 : 1). The National Electrical Manufacturers Association (NEMA) has defined test procedures for measuring the contrast ratio [NEMA, 1992]. The detective quantum efficiency (DQE), which is a measure of the efficiency with which the image intensifier utilizes the x-ray energy incident on it, is in the neighborhood of 65% (400  $\mu\text{m}$  phosphor thickness, 60 keV). A tabulation of the specifications of several commercially available image intensifiers has been published by Siedband [1994].

### 10.2.2.3 Optical Distributor

The image present at the image intensifier output phosphor is coupled to the video camera, and any film camera present (e.g., cine), by the optical distributor. The components of the distributor are shown in Figure 10.4. There is an aperture for each camera to allow the light intensity presented to each camera to be adjusted independently. The video camera aperture is usually a motor-driven variable iris, while the film camera aperture is usually fixed. It is important to realize that while the aperture does ensure that the proper light level is presented to the camera, more fundamentally, the aperture determines the x-ray exposure input to the image intensifier. As a result, both the patient exposure and the level of quantum noise in the image are set by the aperture. The noise amplitude in a fluoroscopic or digital angiographic image is inversely proportional to the f-number of the optical system. Because the quantum sink of a properly adjusted fluorographic system is at the input of the image intensifier, the aperture diameter is set, for a given type of examination, to provide the desired level of quantum mottle present in the image. The x-ray exposure factors are then adjusted for each patient, by an automatic exposure control (AEC) system, to produce the proper postaperture light level. However, some video systems do provide for increasing the video camera aperture during fluoroscopy when the maximum entrance exposure does not provide adequate light levels on a large patient.

The beam-splitting mirror was originally meant to provide a moderate-quality video image simultaneous with cine recording in order to monitor the contrast injection during cardiac studies. More recently, as the importance of digital angiography has mushroomed, precision-quality mirrors with higher transmission have been used in order to provide simultaneous diagnostic-quality cine and video. The latest development has been the introduction of *cine-less* digital cardiac systems, in which the video image is the sole recording means. The introduction of these systems has sometimes been accompanied by the claim that a *cine-less* system requires less patient exposure due to the fact that light does not have to be provided to the cine camera. However, a conventional cine system operates with an excess of light (i.e., the cine camera aperture is stopped down). Because the image intensifier input is the quantum sink of the system, exposure is determined by the need to limit quantum mottle, not to maintain a given light level at the image intensifier output. Therefore, the validity of this claim is dubious. It should be noted, however, that because of the difference in spatial resolution capabilities of cine and video, the noise power spectrum of images acquired with equal exposure will be different. It is possible that observers accept a lower exposure in a video image than in the higher-resolution film image.

### 10.2.2.4 Video System

The video system in an angiographic suite consists of several components, including the camera head, camera control unit (CCU), video monitors, and video recording devices. In addition, a digital image processor is integrated with the video system.

The video camera is responsible for signal generation. Traditionally, pickup-tube based cameras (discussed below) have been used. Recently, high resolution (10242), high frame rate (30 frame/sec) charge-coupled device (CCD) video cameras have become available and are replacing tube-based cameras in some angiographic installations. This trend will probably continue. The image quality ramifications are a matter of current research [Blume, 1998]. The advantages of CCD cameras include low-voltage

operation, reliability, little required setup tuning, and freedom from geometric distortions. Frame-charge transfer is the preferred CCD read-out scheme, due to the higher optical fill factor of this configuration.

Video camera pickup tubes used for angiography are of the photoconductive *vidicon-style* of construction. This type of tube uses a low-velocity scanning beam and generates a signal from the recharge of the target by the scanning electron beam. There are several types of vidicon-style tubes in use (Plumbicon, Primicon, Saticon, Newvicon) which differ from each other in the material and configuration used for target construction. There is an unfortunate confusion in terminology because the original vidicon-style tube is referred to simply as a vidicon. The original vidicon has an antimony trisulfide target ( $\text{Sb}_2\text{S}_3$ ) and exhibits such a high degree of lag (image retention) that it is not useful for angiographic work. Even with *low-lag* angiographic cameras, the residual lag can result in artifacts in subtraction images. Light bias is often used to further reduce lag by ensuring that the target surface is not driven to a negative potential by energetic electrons in the scanning beam [Sandrik, 1984].

Image noise in a well-designed system is due to x-ray quantum fluctuations and noise related to signal generation in the video camera. When used for digital angiographic purposes, it is important that the video camera exhibit a high signal-to-noise ratio (at least 60 dB) so that video camera noise does not dominate the low-signal (dark) portions of the image. In order to achieve this, the pickup tube must be run at high beam currents (2 to 3  $\mu\text{A}$ ). Because long-term operation of the tube at these beam currents can result in damage to the target, beam current is usually either blanked when imaging is not being performed, or the current is held at a low level (e.g., 400 nA) and boosted only when high-quality angiographic images are required. All pickup tubes currently in use for angiographic imaging exhibit a linear response to light input (i.e.,  $\gamma = 1$ , where the relationship between signal current  $I$  and image brightness  $B$  is described by a relationship of the form  $I/I_0 = (B/B_0)\gamma$ ). This has the disadvantage that the range in image brightness presented to the camera often exceeds the camera's dynamic range when a highly transmissive portion of the patient's anatomy (e.g., lung) or unattenuated radiation is included in the image field, either saturating the highlights, forcing the rest of the image to a low signal level, or both. To deal with this problem, it is desirable for the operator to mechanically **bolus** the bright area with metal filters, saline bags, etc. Specially constructed filters are available for commonly encountered problems, such as the transmissive region between the patient's legs during runoff studies of the legs, and most vendors provide a controllable metal filter in the x-ray collimator that the operator can position over bright spots with a joystick.

In addition to mechanical bolusing performed by the laboratory staff, most system vendors have incorporated some form of *gamma curve modification* into the systems. Usually performed using analog processing in the CCU, the technique applies a nonlinear transfer curve to the originally linear data. There are two advantages to this technique. First, the CRT of the display monitor has reduced gain at low signal, so imposing a transfer function with  $\gamma \approx 0.5$  via gamma-curve modification provides a better match between the video signal and the display monitor. Second, if the modification is performed prior to digitization, a  $\gamma < 1$  results in a more constant ratio between the ADC step size and the image noise amplitude across the full range of the video signal. This results in less contouring in the dark portions of the digital image, especially in images that have been spatially filtered. It is important to note, however, that gamma-curve modification does not eliminate the desirable effects of mechanically bolusing the image field prior to image acquisition. This is so because bolusing allows more photon flux to be selectively applied to the more attenuating regions of the patient, which decreases both quantum and video noise in those regions. Bolusing is especially important for subtraction imaging.

The video system characteristic most apparent to the user is the method employed in scanning the image. Prior to the advent of the digital angiography, EIA RS-170 video (525-line, 30 Hz frames, 2:1 interlace) was the predominant standard used for fluoroscopic systems in the United States. However, this method of scanning has definite disadvantages for angiography, including low resolution and image artifacts related to the interlaced format. The inclusion of a digital image processor in the imaging chain, functioning as an image buffer, allows the scanning mode to be tailored to the angiographic procedure. Many of the important video scanning modes used for angiographic work are dependent on the ability of image processors to perform scan conversion operations. Two typical *scan conversion* operations are progressive-to-interlaced conversion and **upscanning**. Progressive-to-interlaced scan conversion allows **progressive**

**FIGURE 10.5** Timing diagram for image acquisition using the pulsed-progressive mode. (From Van Lysel M.S. In, S. Baum (Ed.), *Abrams' Angiography*, 4th ed. Boston, Little, Brown. With permission.)

**scanning** (also referred to as *sequential scanning*) to be used for image acquisition and interlaced scanning for image display. Progressive scanning is a noninterlaced scan mode in which all the lines are read out in a single vertical scan. Progressive scanning is especially necessary when imaging moving arteries, such as during coronary angiography [Seibert et al., 1984]. In noncardiac work, progressive scan acquisition is usually combined with beam blanking. Beam blanking refers to the condition in which the pickup tube beam current is blanked (turned off) for one or more integer number of frames. This mode is used in order to allow the image to integrate on the camera target prior to readout (Figure 10.5). In this way, x-ray pulses shorter than one frame period can be acquired without scanning artifacts, and x-ray pulses longer than one frame period can be used in order to increase the x-ray quantum statistics of an image. Upscanning refers to the acquisition of data at a low line rate (e.g., 525 lines) and the display of that data at a higher line rate (e.g., 1023 lines) [Holmes et al., 1989]. The extra lines are produced by either replication of the actual data or, more commonly, by interpolation (either linear or spline). Upscanning also can be performed in the horizontal direction as well, but this is less typical. Upscanning is used to decrease the demands on the video camera, system bandwidth, and digital storage requirements while improving display contrast and decreasing interfield flicker.

The image buffering capability of a digital system can provide several operations aimed at reducing patient exposure. If fluoroscopy is performed with pulsed rather than continuous x-rays, then the operator has the freedom to choose the frame rate. During **pulsed-progressive fluoroscopy**, the digital system provides for display refresh without flicker. Frame rates of less than 30 fps can result in lower patient exposure, though; because of the phenomenon of eye integration, the x-ray exposure per pulse must be increased as the frame rate drops in order to maintain low contrast detectability [Aufrecht et al., 1994]. *Last image hold*, which stores and displays the last acquired fluoroscopic frame, also can result in an exposure reduction. Combining last image hold with graphic overlays allows collimator shutters and bolus filters to be positioned with the x-rays turned off.

**FIGURE 10.6** Detector modulation transfer function, including limits due to the image intensifier (II), video camera (TV), and sampling, including the antialiasing filter (pixels). Figures are for the 6.5-in. image intensifier mode for 512- and 1024-pixel matrices. In both cases, the total detector MTF is given by the solid line. Data used for this figure from Verhoeven [1985].

### 10.2.3 Digital Angiography

Digital imaging technology has quickly replaced film-based recording for most angiographic procedures. Digital image processing provides the ability to manipulate the contrast and spatial-frequency characteristics of the angiographic image, as well as providing immediate access to the image data during the procedure.

The rapid application of digital imaging technology to the angiographic procedure was facilitated by the fact that the image intensifier and video camera imaging chain was already in use when digital imaging appeared. It is a relatively simple matter to digitize the video camera output. Theoretically, additional noise is added to the image due to quantization errors associated with the digitization process. This additional noise can be kept insignificantly small by using a sufficient number of digital levels so that the amplitude of one digital level is approximately equal to the amplitude of the standard deviation in image values associated with the noise (x-ray quantum and electronic noise) in the image prior to digitization [Kruger et al., 1981]. To meet this condition, most digital angiographic systems employ a 10-bit (1024-level) analog-to-digital convertor (ADC). Those systems which are designed to digitize high-noise (i.e., low x-ray exposure) images exclusively can employ an 8-bit (256-level) ADC. Such systems include those designed for cardiac and fluoroscopic applications.

The spatial resolution of a digital angiographic image is determined by several factors, including the size of the x-ray tube focal spot, the modulation transfer function of the image intensifier-video camera chain, and the size of the pixel matrix. The typical image matrix dimensions for non-cardiac digital angiographic images is  $1024 \times 1024$ . Cardiac systems use  $512 \times 512$ ,  $1024(H) \times 512(V)$ , or  $1024 \times 1024$ . Sampling rates required to digitize  $512^2$  and  $1024^2$  matrices in the 33-msec frame period of conventional video are 10 and 40 MHz, respectively. Figure 10.6 shows an example of the detector MTF of a digital angiographic system. The product of the image intensifier and video system MTF constitute the presampling MTF [Fujita et al., 1985]. It is seen that the effect of sampling with a 512-pixel matrix is to truncate the high-frequency tail of the presampling MTF, while a 1024-pixel matrix imposes few additional limitations beyond that associated with the analog components (especially for small image intensifier modes) [Verhoeven, 1985]. However, because of blurring associated with the x-ray tube focal spot, the full advantage of the higher density pixel matrix can rarely be realized, clinically (Figure 10.7).

#### 10.2.3.1 Digital Image Processor

The digital image processor found in a modern angiographic suite is a dedicated device designed specially to meet the demands of the angiographic procedure. Hardware is structured as a pipeline processor to perform real-time processing at video rates. Image-subtraction, integration, spatial-filtration, and temporal-filtration algorithms are hardwired to meet this requirement. Lookup tables (LUTs) are used to

**FIGURE 10.7** Experimental determination of the limiting resolution (high-contrast object and high x-ray exposure) for 512- and 1024-pixel matrices, focal spots of actual dimensions 1.0 and 1.5 mm, and a 6.5-in. image intensifier mode, as a function of geometric magnification. (From Mistretta, C.A. and Pepler, W.W. 1988. *Am. J. Card. Imag.* 2: 26. With permission.)

perform intensity transformations (e.g., contrast enhancement and logarithmic transformation). A more general-purpose host computer is used to control the pipeline processor and x-ray generator, respond to user input, and perform nonreal-time image manipulations.

The most clinically important image-processing algorithm is temporal subtraction (DSA). Subtraction imaging is used for most vascular studies. Subtraction allows approximately a factor of 2 reduction in the amount of injected contrast material. As a result, DSA studies can be performed with less contrast load and with smaller catheters than film/screen angiography. The primary limitation of DSA is a susceptibility to misregistration artifacts resulting from patient motion. Some procedures that are particularly susceptible to motion artifacts are routinely performed in a nonsubtracted mode. Unsubtracted digital angiographic studies are usually performed with the same amount of contrast material as film/screen studies. Cardiac angiography is one procedure that is generally performed without subtraction, although in any particular study, if patient and respiratory motion are absent, it is possible to obtain high-quality time subtractions using phase-matched mask subtractions in which the preinjection mask and postinjection contrast images are matched with respect to cardiac phase. In order to do this efficiently, it is necessary to digitize the ECG signal along with the image data.

Additional examples of unsubtracted digital angiographic studies are those in uncooperative patients (e.g., trauma) and digital runoff studies of the vessels in the leg. In a digital runoff study it is necessary to follow the bolus down the legs by moving the patient (or the image gantry). This motion causes difficulties with both mask registration and uniform exposure intensities between the mask and contrast images. The high contrast sensitivity of DSA is valuable for runoff studies, however, because the small vessels and slow flow in the lower extremities can make vessel visualization difficult. Recently, making use of programmed table (or gantry) motion and pixel-shifting strategies, x-ray vendors have begun to offer a viable digital subtraction runoff mode.

In addition to subtraction angiography, two filtration algorithms have become clinically important. The first is high-pass spatial filtration for the purposes of providing edge enhancement. Real-time edge enhancement of fluoroscopy is especially important for interventional procedures, such as angioplasty, where the task requires visualization of high-frequency objects such as vessel edges and guidewires. Because increasing the degree of edge enhancement also increases image noise, operator control of the degree of enhancement (accomplished by adjusting the size and weighing of the convolution kernel) is an important feature.

The second filtration algorithm often available from a digital angiographic system is low-pass temporal filtration (recursive filtering) [Rowlands, 1992]. Temporal filtration is used to reduce quantum noise levels in fluoroscopic images without increasing patient exposure. Recursive filtering is a more desirable method than simple image integration because it requires only two memory planes and because it is a simple matter to turn the filtering algorithm off, on a pixel-by-pixel basis, when motion is detected. Motion-detection circuits monitor the frame-to-frame change in pixel values and assume that an object has moved into or out of the pixel if the change exceeds a preset threshold.

### 10.2.3.2 Image Storage

Storage needs during the angiographic procedure are easily met by modern hard drives. These often are configured to provide real-time (i.e., video rate) storage. The immediate access to images provided by real-time disk technology is one of the major advantages of digital angiography over film. Not only is it unnecessary to wait for film to be developed, but review of the image data after the patient's procedure is completed is facilitated by directories and specialized review software. For example, a popular image menu feature is the presentation to users of a low-resolution collage of available images from which they may select a single image or entire run for full-resolution display.

While online storage of recent studies is a strength of digital angiography, long-term (archival) storage is a weakness. Archival devices provided by vendors are generally proprietary devices that make use of various recording media. There is an established communications protocol (ACR-NEMA) [NEMA, 1993] for network transfer of images. For the time being, while large institutions and teaching hospitals are investing in sophisticated digital **picture archiving and communications systems (PACS)**, archival needs at most institutions are met by storage of hardcopy films generated from the digital images. Hardcopy devices include multifORMAT cameras (laser or video) and video thermal printers. Laser cameras, using either an analog or a digital interface to the digital angiographic unit, can provide diagnostic-quality, large-format, high-contrast, high-resolution films. MultifORMAT video cameras, which expose the film with a CRT, are a less expensive method of generating diagnostic-quality images but are also more susceptible to drift and geometric distortions. Thermal printer images are generally used as convenient method to generate temporary hardcopy images.

Cardiac angiography labs have long employed a similar method, referred to as **parallel cine**, in which both digital and cine images are recorded simultaneously by use of the semitransparent mirror in the image intensifier optical distributor. Immediate diagnosis would be performed off the digital monitor while the 35-mm film would provide archival storage and the ability to share the image data with other institutions. However, due to the promulgation of an image transfer standard using the recordable CD (CD-R), many laboratories are abandoning cine film. While CD-R cannot replay images at full real-time rates, the read-rate (>1 MB/sec) is sufficient to load old data quickly from CD-R to a workstation hard drive for review. Low volume laboratories can use CD-R as an archival storage method. Higher volume labs are installing networked video file servers to provide online or near-line access to archived patient studies.

## 10.2.4 Summary

For decades, x-ray projection film/screen angiography was the only invasive modality available for the diagnosis of vascular disease. Now several imaging modalities are available to study the cardiovascular system, most of which are less invasive than x-ray projection angiography. However, conventional angiography also

has changed dramatically during the last decade. Digital angiography has replaced film/screen angiography in most applications. In addition, the use and capabilities of transluminal interventional techniques have mushroomed, and digital angiographic processor modes have expanded significantly in support of these interventional procedures. As a consequence, while less invasive technologies, such as MR angiography, make inroads into conventional angiography's diagnostic applications, it is likely that x-ray projection angiography will remain an important clinical modality for many years to come.

## Defining Terms

- Bolus:** This term has two, independent definition (1) material placed in a portion of the x-ray beam to reduce the sense dynamic range and (2) the injection contrast material.
- Digital subtraction angiography (DSA):** Methodology in which digitized angiographic images are subtracted in order to provide contrast enhancement of the opacified vasculature. Clinically, temporal subtraction is the algorithm used, though energy subtraction methods also fall under the generic term DSA.
- Parallel cine:** The simultaneous recording of digital and cine-film images during cardiac angiography. In this mode, digital image acquisition provides diagnostic-quality images.
- Picture archiving and communications systems (PACS):** Digital system or network for the electronic storage and retrieval of patient images and data.
- Progressive scanning:** Video raster scan method in which all horizontal lines are read out in a single vertical scan of the video camera target.
- Pulsed-progressive fluoroscopy:** Method of acquiring fluoroscopic images in which x-rays are produced in discrete pulses coincident with the vertical retrace period of the video camera. The video camera is then read out using progressive scanning. This compares with the older fluoroscopic method of producing x-rays continuously, coupled with interlaced video camera scanning.
- Temporal subtraction:** Also known as time subtraction or mask-mode subtraction. A subtraction mode in which an unopacified image (the mask, usually acquired prior to injection) is subtracted from an opacified image.
- Upscanning:** Scan conversion method in which the number of pixels or video lines displayed is higher (usually by a factor of 2) than those actually acquired from the video camera. Extra display data are produced by either replication or interpolation of the acquired data.

## 10.3 Mammography

---

### *Martin J. Yaffe*

Mammography is an x-ray imaging procedure for examination of the breast. It is used primarily for the detection and diagnosis of breast cancer, but also for pre-surgical localization of suspicious areas and in the guidance of needle biopsies.

Breast cancer is a major killer of women. Approximately 179,000 women were diagnosed with breast cancer in the United States in 1998 and 43,500 women died of this disease [Landis, 1998]. Its cause is not currently known; however, it has been demonstrated that **survival** is greatly improved if disease is detected at an early stage [Tabar, 1993; Smart, 1993]. Mammography is at present the most effective means of detecting early stage breast cancer. It is used both for investigating symptomatic patients (diagnostic mammography) and for **screening** of asymptomatic women in selected age groups.

Breast cancer is detected on the basis of four types of signs on the mammogram:

1. The characteristic morphology of a tumor mass
2. Certain presentations of mineral deposits as specks called microcalcifications
3. Architectural distortion of normal tissue patterns caused by the disease
4. Asymmetry between corresponding regions of images of the left and right breast

### 10.3.1 Principles of Mammography

The mammogram is an x-ray shadowgram formed when x-rays from a quasi-point source irradiate the breast and the transmitted x-rays are recorded by an **image receptor**. Because of the spreading of the x-rays from the source, structures are magnified as they are projected onto the image receptor. The signal is a result of differential attenuation of x-rays along paths passing through the structures of the breast.

The essential features of image quality are summarized in Figure 10.8. This is a one-dimensional profile of x-ray transmission through a simplified computer model of the breast [Fahrig, 1992], illustrated in Figure 10.9. A region of reduced transmission corresponding to a structure of interest such as a tumor, a calcification, or normal *fibroglandular* tissue is shown. The imaging system must have sufficient *spatial resolution* to delineate the edges of fine structures in the breast. Structural detail as small as 50  $\mu\text{m}$  must be adequately resolved. Variation in x-ray attenuation among tissue structures in the breast gives rise to contrast. The detectability of structures providing subtle contrast is impaired, however, by an overall random fluctuation in the profile, referred to as mottle or noise. Because the breast is sensitive to ionizing radiation, which at least for high doses is known to cause breast cancer, it is desirable to use the lowest radiation dose compatible with excellent image quality. The components of the imaging system will be described and their design will be related to the imaging performance factors discussed in this section.

**FIGURE 10.8** Profile of a simple x-ray projection image illustrating the role of contrast, spatial resolution, and noise in mammographic image quality.

**FIGURE 10.9** Simplified computer model of the mammographic image acquisition process.

### 10.3.2 Physics of Image Formation

In the model of Figure 10.9, an “average” breast composed of 50% adipose tissue and 50% **fibroglandular tissue** is considered. For the simplified case of monoenergetic x-rays of energy,  $E$ , the number of x-rays recorded in a fixed area of the image is proportional to

$$N_B = N_0(E)e^{-\mu T} \quad (10.1)$$

in the “background” and

$$N_L = N_0(E)e^{-[\mu(T-t)+\mu't]} \quad (10.2)$$

in the shadow of the lesion or other structure of interest. In Equation 61.1 and Equation 61.2,  $N_0(E)$  is the number of x-rays that would be recorded in the absence of tissue in the beam,  $\mu$  and  $\mu'$  are the attenuation coefficients of the breast tissue and the lesion, respectively,  $T$  is the thickness of the breast, and  $t$  is the thickness of the lesion.

The difference in x-ray transmission gives rise to subject contrast which can be defined as:

$$C_0 = \frac{N_B - N_L}{N_B + N_L} \quad (10.3)$$

For the case of monoenergetic x-rays and temporarily ignoring scattered radiation,

$$\frac{1 - e^{-[\mu' - \mu]t}}{1 + e^{-[\mu' - \mu]t}} \quad (10.4)$$

that is, contrast would depend only on the thickness of the lesion and the difference between its attenuation coefficient and that of the background material. These are not valid assumptions and in actuality contrast also depends on  $\mu$  and  $T$ .

Shown in Figure 10.10 are x-ray attenuation coefficients measured vs. energy on samples of three types of materials found in the breast: adipose tissue, normal fibroglandular breast tissue, and infiltrating ductal carcinoma (one type of breast tumor) [Johns, 1987]. Both the attenuation coefficients themselves and their difference ( $\mu' - \mu$ ) decrease with increasing  $E$ . As shown in Figure 10.11, which is based on Equation 10.4, this causes  $C_s$  to fall as x-ray energy increases. Note that the subject contrast of even small calcifications in the breast is greater than that for a tumor because of the greater difference in attenuation coefficient between calcium and breast tissue.

For a given image recording system (image receptor), a proper exposure requires a specific value of x-ray energy transmitted by the breast and incident on the receptor, that is, a specific value of  $N_B$ . The breast entrance skin exposure<sup>1</sup> (ESE) required to produce an image is, therefore, proportional to

$$N_0 = N_B(E)e^{+\mu T} \quad (10.5)$$

Because  $\mu$  decreases with energy, the required exposure for constant signal at the image receptor,  $N_B$ , will increase if  $E$  is reduced to improve image contrast. A better measure of the risk of radiation-induced breast cancer than ESE is the mean glandular dose (MGD) [BEIR V, 1990]. MGD is calculated as the product of the ESE and a factor, obtained experimentally or by Monte Carlo radiation transport calculations, which converts from incident exposure to dose [Wu, 1991, 1994]. The conversion factor increases with  $E$  so that MGD does not fall as quickly with energy as does entrance exposure. The trade-off between image contrast and radiation dose necessitates important compromises in establishing mammographic operating conditions.

<sup>1</sup>Exposure is expressed in Roentgens (R) (which is not an SI unit) or in Coulombs of ionization collected per kilogram of air.

FIGURE 10.10 Measured x-ray linear attenuation coefficients of breast fibroglandular tissue, breast fat, and infiltrating ductal carcinoma plotted vs. x-ray energy.

FIGURE 10.11 Dependence of mammographic subject contrast on x-ray energy.

### 10.3.3 Equipment

The mammography unit consists of an x-ray tube and an image receptor mounted on opposite sides of a mechanical assembly or gantry. Because the breast must be imaged from different aspects and to accommodate patients of different height, the assembly can be adjusted in a vertical axis and rotated about a horizontal axis as shown in Figure 10.12.

Most general radiography equipment is designed such that the image field is centered below the x-ray source. In mammography, the system's geometry is arranged as in Figure 10.13a where a vertical line from the x-ray source grazes the chest wall of the patient and intersects orthogonally with the edge of the image receptor closest to the patient. If the x-ray beam were centered over the breast as in Figure 10.13b, some of the tissue near the chest wall would be projected inside of the patient where it could not be recorded.

FIGURE 10.12 Schematic diagram of a dedicated mammography machine.

FIGURE 10.13 Geometric arrangement of system components in mammography. (a) Correct alignment provides good tissue coverage, (b) incorrect alignment causes tissue near the chest wall not to be imaged.

Radiation leaving the x-ray tube passes through a metallic spectral-shaping filter, a beam-defining aperture, and a plate which compresses the breast. Those rays transmitted through the breast are incident on an antiscatter “**grid**” and then strike the image receptor where they interact and deposit most of their energy locally. A fraction of the x-rays pass through the receptor without interaction and impinge upon a sensor which is used to activate the automatic exposure control mechanism of the unit.

### 10.3.3.1 X-Ray Source

Practical monoenergetic x-ray sources are not available and the x-rays used in mammography arise from bombardment of a metal target by electrons in a hot-cathode vacuum tube. The x-rays are emitted from the target over a spectrum of energies, ranging up to the peak kilovoltage applied to the x-ray tube. Typically, the x-ray tube employs a rotating anode design in which electrons from the cathode strike the anode target material at a small angle ( $0$  to  $16^\circ$ ) from normal incidence (Figure 10.14). Over 99% of the energy from the electrons is dissipated as heat in the anode. The angled surface and the distribution of the electron bombardment along the circumference of the rotating anode disk allows the energy to be spread over a larger area of target material while presenting a much smaller effective **focal spot** as viewed from the imaging plane. On modern equipment, the typical “nominal” focal spot size for normal contact mammography is 0.3 mm, while the smaller spot used primarily for magnification is 0.1 mm. The specifications for x-ray focal spot size tolerance, established by NEMA (National Electrical Manufacturers Association) or the IEC (International Electrotechnical Commission) allow the effective focal spot size to be considerably larger than these nominal sizes. For example, the NEMA specification allows the effective focal spot size to be 0.45 mm in width and 0.65 mm in length for a nominal 0.3 mm spot and 0.15 mm in each dimension for a nominal 0.1 mm spot.

The nominal focal spot size is defined relative to the effective spot size at a “reference axis.” As shown in Figure 10.14, this reference axis, which may vary from manufacturer to manufacturer, is normally specified at some mid-point in the image. The effective size of the focal spot will monotonically increase from the anode side to the cathode side of the imaging field. Normally, x-ray tubes are arranged such that the cathode side of the tube is adjacent to the patient’s chest wall, since the highest intensity of x-rays is available at the cathode side, and the attenuation of x-rays by the patient is generally greater near the chest wall of the image.

The spatial resolution capability of the imaging system is partially determined by the effective size of the focal spot and by the degree of magnification of the anatomy at any plane in the breast. This is illustrated

**FIGURE 10.14** Angled-target x-ray source provides improved heat loading but causes effective focal spot size to vary across the image.

FIGURE 10.15 Dependence of focal spot unsharpness on focal spot size and magnification factor.

in Figure 10.15 where, by similar triangles, the unsharpness region due to the finite size of the focal spot is linearly related to the effective size of the spot and to the ratio of OID to SOD, where SOD is the source-object distance and OID is the object-image receptor distance. Because the breast is a three-dimensional structure, this ratio and, therefore, the unsharpness will vary for different planes within the breast.

The size of the focal spot determines the heat loading capability of the x-ray tube target. For smaller focal spots, the current through the x-ray tube must be reduced, necessitating increased exposure times and the possibility of loss of resolution due to motion of anatomical structures. Loss of geometric resolution can be controlled in part by minimizing OID/SOD, that is, by designing the equipment with greater source-breast distances, by minimizing space between the breast and the image receptor, and by compressing the breast to reduce its overall thickness.

Magnification is often used intentionally to improve the signal-to-noise ratio of the image. This is accomplished by elevating the breast above the image receptor, in effect reducing SOD and increasing OID. Under these conditions, resolution is invariably limited by focal spot size and use of a small spot for magnification imaging (typically a nominal size of 0.1 mm) is critical.

Since monoenergetic x-rays are not available, one attempts to define a spectrum providing energies which give a reasonable compromise between radiation dose and image contrast. The spectral shape can be controlled by adjustment of the kilovoltage, choice of the target material, and the type and thickness of metallic filter placed between the x-ray tube and the breast.

Based on models of the imaging problem in mammography, it has been suggested that the optimum energy for imaging lies between 18 and 23 keV, depending on the thickness and composition of the breast [Beaman, 1982]. It has been found that for the breast of typical thickness and composition, the characteristic x-rays from molybdenum at 17.4 and 19.6 keV provide good imaging performance. For this reason, molybdenum target x-ray tubes are used on the vast majority of mammography machines.

Most mammography tubes use beryllium exit windows between the evacuated tube and the outside world since glass or other metals used in general purpose tubes would provide excessive attenuation of the useful energies for mammography. Figure 10.16 compares tungsten target and molybdenum target spectra for beryllium window x-ray tubes. Under some conditions, tungsten may provide appropriate image quality for mammography; however, it is essential that the intense emission of  $L$  radiation from tungsten be filtered from the beam before it is incident upon the breast, since extremely high doses to the skin would result from this radiation without useful contribution to the mammogram.

FIGURE 10.16 Comparison of tungsten and molybdenum target x-ray spectra.

FIGURE 10.17 Molybdenum target spectrum filtered by 0.03 mm Mo foil.

### 10.3.3.2 Filtration of the X-Ray Beam

In conventional radiology, filters made of aluminum or copper are used to provide selective removal of low x-ray energies from the beam before it is incident upon the patient. In mammography, particularly when a molybdenum anode x-ray tube is employed, a molybdenum filter 20–35  $\mu\text{m}$  thick is generally used. This filter attenuates x-rays both at low energies and those above its own *K*-absorption edge allowing the molybdenum characteristic x-rays from the target to pass through the filter with relatively high efficiency. As illustrated in Figure 10.17, this *K* edge filtration results in a spectrum enriched with x-ray energies in the range of 17–20 keV.

Although this spectrum is relatively well suited for imaging the breast of average attenuation, slightly higher energies are desirable for imaging dense thicker breasts. Because the molybdenum target spectrum is

so heavily influenced by the characteristic x-rays, an increase in the kilovoltage alone does not substantially change the shape of the spectrum. The beam can be “hardened,” however, by employing filters of higher atomic number than molybdenum. For example, rhodium (atomic no. 45) has a  $K$  absorption edge at 23 keV, providing strong attenuation both for x-rays above this energy and for those at substantially lower energies. Used with a molybdenum target x-ray tube and slightly increased kilovolt, it provides a spectrum with increased penetration (reduced dose) compared to the Mo/Mo combination.

It is possible to go further in optimizing imaging performance, by “tuning” the effective spectral energy by using other target materials in combination with appropriate  $K$ -edge filters [Jennings, 1993]. One manufacturer employs an x-ray tube incorporating both molybdenum and rhodium targets, where the electron beam can be directed toward one or the other of these materials [Heidsieck, 1991]. With this system, the filter material (rhodium, molybdenum, etc.) can be varied to suit the target that has been selected. Similarly, work has been reported on  $K$ -edge filtration of tungsten spectra [Desponds, 1991], where the lack of pronounced  $K$  characteristic peaks provides more flexibility in spectral shaping with filters.

### 10.3.3.3 Compression Device

There are several reasons for applying firm (but not necessarily painful) compression to the breast during the examination. Compression causes the different tissues to be spread out, minimizing superposition from different planes and thereby improving a conspicuity of structures. As will be discussed later, scattered radiation can degrade contrast in the mammogram. The use of compression decreases the ratio of scattered to directly transmitted radiation reaching the image receptor. Compression also decreases the distance from any plane within the breast to the image receptor (i.e., OID) and in this way reduces geometric unsharpness. The compressed breast provides lower overall attenuation to the incident x-ray beam, allowing the radiation dose to be reduced. The compressed breast also provides more uniform attenuation over the image. This reduces the exposure range which must be recorded by the imaging system, allowing more flexibility in choice of films to be used. Finally, compression provides a clamping action which reduces anatomical motion during the exposure reducing this source of image unsharpness.

It is important that the compression plate allows the breast to be compressed parallel to the image receptor, and that the edge of the plate at the chest wall be straight and aligned with both the focal spot and image receptor to maximize the amount of breast tissue which is included in the image (see Figure 10.13).

### 10.3.3.4 Antiscatter Grid

Lower x-ray energies are used for mammography than for other radiological examinations. At these energies, the probability of photoelectric interactions within the breast is significant. Nevertheless, the probability of Compton scattering of x-rays within the breast is still quite high. Scattered radiation recorded by the image receptor has the effect of creating a quasi-uniform haze on the image and causes the subject contrast to be reduced to

$$C_s = \frac{C_0}{1 + \text{SPR}} \quad (10.6)$$

where  $C_0$  is the contrast in the absence of scattered radiation, given by Equation 10.4 and SPR is the scatter-to-primary (directly transmitted) x-ray ratio at the location of interest in the image. In the absence of an anti-scatter device, 37 to 50% of the total radiation incident on the image receptor would have experienced a scattering interaction within the breast, that is, the scatter-to-primary ratio would be 0.6 : 1.0. In addition to contrast reduction, the recording of scattered radiation uses up part of the dynamic range of the image receptor and adds statistical noise to the image.

Antiscatter *grids* have been designed for mammography. These are composed of linear lead (Pb) septa separated by a rigid interspace material. Generally, the grid septa are not strictly parallel but focused (toward the x-ray source). Because the primary x-rays all travel along direct lines from the x-ray source to the image receptor, while the scatter diverges from points within the breast, the grid presents a smaller

acceptance aperture to scattered radiation than to primary radiation and thereby discriminates against scattered radiation. Grids are characterized by their *grid ratio* (ratio of the path length through the interspace material to the interseptal width) which typically ranges from 3.5:1 to 5:1. When a grid is used, the SPR is reduced typically by a factor of about 5, leading in most cases to a substantial improvement in image contrast [Wagner, 1991].

On modern mammography equipment, the grid is an integral part of the system, and during x-ray exposure is moved to blur the image of the grid septa to avoid a distracting pattern in the mammogram. It is important that this motion be uniform and of sufficient amplitude to avoid nonuniformities in the image, particularly for short exposures that occur when the breast is relatively lucent.

Because of absorption of primary radiation by the septa and by the interspace material, part of the primary radiation transmitted by the patient does not arrive at the image receptor. In addition, by removing some of the scattered radiation, the grid causes the overall radiation fluence to be reduced from that which would be obtained in its absence. To obtain a radiograph of proper optical density, the entrance exposure to the patient must be increased by a factor known as the Bucky factor to compensate for these losses. Typical Bucky factors are in the range of 2 to 3.

A linear grid does not provide scatter rejection for those quanta traveling in planes parallel to the septa. Recently a crossed grid that consists of septa that run in orthogonal directions has been introduced for this purpose. The improved scatter rejection is accomplished at doses comparable to those required with a linear grid, because the interspace material of the crossed grid is air rather than solid. To avoid artifacts, the grid is moved in a very precise way during the exposure to ensure a uniform blurring of the image of the grid itself.

### 10.3.3.5 Image Receptor

#### 10.3.3.5.1 Fluorescent Screens

When first introduced, mammography was carried out using direct exposure radiographic film in order to obtain the high spatial resolution required. Since the mid-1970s, high resolution fluorescent screens have been used to convert the x-ray pattern from the breast into an optical image. These screens are used in conjunction with single-coated radiographic film, and the configuration is shown in Figure 10.18. With this arrangement, the x-rays pass through the cover of a light-tight cassette and the film to impinge upon the screen. Absorption is exponential, so that a large fraction of the x-rays are absorbed near the entrance surface of the screen. The phosphor crystals which absorb the energy produce light in an isotropic distribution. Because the film emulsion is pressed tightly against the entrance surface of the screen, the

FIGURE 10.18 Design of a screen-film image receptor for mammography.

majority of the light quanta have only a short distance to travel to reach the film. Light quanta traveling longer distances have an opportunity to spread laterally (see Figure 10.18), and in this way degrade the spatial resolution. To discriminate against light quanta which travel along these longer oblique paths, the phosphor material of the screen is generally treated with a dye which absorbs much of this light, giving rise to a sharper image. A typical phosphor used for mammography is gadolinium oxysulphide ( $\text{Gd}_2\text{O}_2\text{S}$ ). Although the *K*-absorption edge of gadolinium occurs at too high an energy to be useful in mammography, the phosphor material is dense ( $7.44 \text{ g/cm}^3$ ) so that the **quantum efficiency** (the fraction of incident x-rays which interact with the screen), is good (about 60%). Also, the **conversion efficiency** (fraction of the absorbed x-ray energy converted to light) is relatively high. The light emitted from the fluorescent screen is essentially linearly dependent upon the total amount of energy deposited by x-rays within the screen.

#### 10.3.3.5.2 Film

The photographic film emulsion for mammography is designed with a characteristic curve such as that shown in Figure 10.19, which is a plot of the optical density (blackness) provided by the processed film vs. the logarithm of the x-ray exposure to the screen. Film provides nonlinear input–output transfer characteristics. The local gradient of this curve controls the display contrast presented to the radiologist. Where the curve is of shallow gradient, a given increment of radiation exposure provides little change in optical density, rendering structures imaged in this part of the curve difficult to visualize. Where the curve is steep, the film provides excellent image contrast. The range of exposures over which contrast is appreciable is referred to as the latitude of the film. Because the film is constrained between two optical density values — the *base + fog* density of the film, where no intentional x-ray exposure has resulted, and the maximum density provided by the emulsion — there is a compromise between maximum gradient of the film and the latitude that it provides. For this reason, some regions of the mammogram will generally be underexposed or overexposed, that is, rendered with sub-optimal contrast.

#### 10.3.3.5.3 Film Processing

Mammography film is processed in an automatic processor similar to that used for general radiographic films. It is important that the development temperature, time, and rate of replenishment of the developer

FIGURE 10.19 Characteristic curve of a mammographic screen-film image receptor.

chemistry be compatible with the type of film emulsion used and be designed to maintain good contrast of the film.

#### 10.3.3.6 Noise and Dose

Noise in mammography results primarily from two sources — the random absorption of x-rays in the detector and the granularity associated with the screen and the film emulsion. The first, commonly known as quantum noise, is governed by Poisson statistics so that for a given area of image the standard deviation in the number of x-rays recorded is equal to the square root of the mean number recorded. In other words, the noise in the image is dependent on both the amount of radiation which strikes the imaging system per unit area, and the quantum efficiency of the imaging system. The quantum efficiency is related to the attenuation coefficient of the phosphor material and the thickness of the screen. In order to maintain high spatial resolution, the screen must be made relatively thin to avoid lateral diffusion of light. The desirability of maintaining a relatively low quantum noise level in the image mandates that the conversion efficiency of the screen material and the sensitivity of the film not be excessively high. With very high conversion efficiency, the image could be produced at low dose but with an inadequate number of quanta contributing to the image. Similarly, film granularity increases as more sensitive films are used, so that again film speed must be limited to maintain high image quality. For current high quality mammographic imaging employing an anti-scatter grid, with films exposed to a mean optical density of at least 1.6, the mean glandular dose to a 5-cm thick compressed breast consisting of 50% fibroglandular and 50% adipose tissue is in the range of 1 to 2 mGy [Conway, 1992].

#### 10.3.3.7 Automatic Exposure Control

It is difficult for the technologist to estimate the attenuation of the breast by inspection and, therefore, modern mammography units are equipped with automatic exposure control (AEC). The AEC radiation sensors are located behind the image receptor so that they do not cast a shadow on the image. The sensors measure the x-ray fluence transmitted through both the breast and the receptor and provide a signal which can be used to discontinue the exposure when a certain preset amount of radiation has been received by the image receptor. The location of the sensor must be adjustable so that it can be placed behind the appropriate region of the breast in order to obtain proper image density. AEC devices must be calibrated so that constant image optical density results are independent of variations in breast attenuation, kilovoltage setting, or field size. With modern equipment, automatic exposure control is generally microprocessor-based so that relatively sophisticated corrections can be made during the exposure for the above effects and for *reciprocity law* failure of the film.

##### 10.3.3.7.1 Automatic Kilovoltage Control

Many modern mammography units also incorporate automatic control of the kilovoltage or target/filter/kilovoltage combination. Penetration through the breast depends on both breast thickness and composition. For a breast that is dense, it is possible that a very long exposure time would be required to achieve adequate film blackening. This results in high dose to the breast and possibly blur due to anatomical motion. It is possible to sense the compressed breast thickness and the transmitted exposure rate and to employ an algorithm to automatically choose the x-ray target and/or beam filter as well as the kilovoltage.

### 10.3.4 Quality Control

Mammography is one of the most technically demanding radiographic procedures, and in order to obtain optimal results, all components of the system must be operating properly. Recognizing this, the American College of Radiology implemented and administers a Mammography Accreditation Program [McClelland, 1991], which evaluates both technical and personnel-related factors in facilities applying for accreditation.

In order to verify proper operation, a rigorous quality control program should be in effect. In fact, the U.S. Mammography Quality Standards Act stipulates that a quality control program must be in place in all facilities performing mammography. A program of tests (summarized in Table 10.1) and methods

**TABLE 10.1** Mammographic Quality Control Minimum Test Frequencies

Test	Performed By	Minimum Frequency	
Darkroom cleanliness	Radiologic technologist	Daily	
Processor quality control		Daily	
Screen cleanliness		Weekly	
Viewboxes and viewing conditions		Weekly	
Phantom images		Weekly	
Visual check list		Monthly	
Repeat analysis		Quarterly	
Analysis of fixer retention in film		Quarterly	
Darkroom fog		Semi-annually	
Screen-film contact		Semi-annually	
Compression		Semi-annually	
Mammographic unit assembly evaluation		Medical physicist	Annually
Collimation assessment			Annually
Focal spot size performance			Annually
kVp accuracy/reproducibility	Annually

for performing them are contained in the quality control manuals for mammography published by the American College of Radiology [Hendrick, 1999].

### 10.3.5 Stereotactic Biopsy Devices

Stereoscopic x-ray imaging techniques are currently used for the guidance of needle “core” biopsies. These procedures can be used to investigate suspicious mammographic or clinical findings without the need for surgical excisional biopsies, resulting in reduced patient risk, discomfort, and cost. In these stereotactic biopsies, the gantry of a mammography machine is modified to allow angulated views of the breast (typically  $\pm 15^\circ$  from normal incidence) to be achieved. From measurements obtained from these images, the three-dimensional location of a suspicious lesion is determined and a needle equipped with a spring-loaded cutting device can be accurately placed in the breast to obtain tissue samples. While this procedure can be performed on an upright mammography unit, special dedicated systems have recently been introduced to allow its performance with the patient lying prone on a table. The accuracy of sampling the appropriate tissue depends critically on the alignment of the system components and the quality of the images produced. A thorough review of stereotactic imaging, including recommended quality control procedures is given by Hendrick and Parker [1994].

### 10.3.6 Digital Mammography

There are several technical factors associated with screen-film mammography which limit the ability to display the finest or most subtle details, and produce images with the most efficient use of radiation dose to the patient. In screen-film mammography, the film must act as an image acquisition detector as well as

FIGURE 10.20 Schematic representation of a digital mammography system.

a storage and display device. Because of its sigmoidal shape, the range of x-ray exposures over which the film display gradient is significant, that is, the image latitude, is limited. If a tumor is located in either a relatively lucent or more opaque region of the breast, then the contrast displayed to the radiologist may be inadequate because of the limited gradient of the film. This is particularly a concern in patients whose breasts contain large amounts of fibroglandular tissue, the so-called dense breast.

Another limitation of film mammography is the effect of structural noise due to the granularity of the film emulsion used to record the image. This impairs the detectability of microcalcifications and other fine structures within the breast. While Poisson quantum noise is unavoidable, it should be possible to virtually eliminate structural noise by technical improvements. Existing screen-film mammography also suffers because of the inefficiency of grids in removing the effects of scattered radiation and with compromises in spatial resolution vs. quantum efficiency inherent in the screen-film image receptor.

Many of the limitations of conventional mammography can be effectively overcome with a digital *mammography* imaging system (Figure 10.20), in which image acquisition, display, and storage are performed independently, allowing optimization of each. For example, acquisition can be performed with low noise, highly linear x-ray detectors, while since the image is stored digitally, it can be displayed with contrast independent of the detector properties and defined by the needs of the radiologist. Whatever image processing techniques are found useful, ranging from simple contrast enhancement to histogram modification and spatial frequency filtering, could conveniently be applied.

The challenges in creating a digital mammography system with improved performance are mainly related to the x-ray detector and the display device. There is active development of high resolution display monitors and hard copy devices to meet the demanding requirements (number of pixels, luminance, speed, multi-image capacity) of displaying digital mammography images, and suitable systems for this purpose should be available in the near future. The detector should have the following characteristics:

1. Efficient absorption of the incident radiation beam
2. Linear response over a wide range of incident radiation intensity
3. Low intrinsic noise
4. Spatial resolution on the order of 10 cycles/mm ( $50 \mu\text{m}$  sampling)
5. Can accommodate at least an  $18 \times 24$  cm and preferably a  $24 \times 30$  cm field size
6. Acceptable imaging time and heat loading of the x-ray tube

Two main approaches have been taken in detector development — area detectors and slot detectors. In the former, the entire image is acquired simultaneously, while in the latter only a portion of the image is acquired at one time and the full image is obtained by scanning the x-ray beam and detector across the breast. Area detectors offer convenient fast image acquisition and could be used with conventional x-ray machines, but may still require a grid, while slot systems are slower and require a scanning x-ray beam, but use relatively simple detectors and have excellent intrinsic efficiency at scatter rejection.

At the time of writing, small-format ( $5 \times 5$  cm) digital systems for guidance of stereotactic breast biopsy procedures are in widespread use. These use a lens or a fiberoptic taper to couple a phosphor to a CCD whose format is approximately square and typically provides  $1 \times 1$  K images with  $50 \mu\text{m}$  pixels (Figure 10.21a). Adjustment of display contrast enhances the localization of the lesion while the immediate display of images (no film processing is required) greatly accelerates the clinical procedure.

Four designs of full breast digital mammography systems are undergoing clinical evaluation. Various detector technologies are being developed and evaluated for use in digital mammography. In three of the systems, x-rays are absorbed by a cesium iodide (CsI) phosphor layer and produce light. In one system, the phosphor is deposited directly on a matrix of about 20002 photodiodes with thin film transistor switches fabricated on a large area amorphous silicon plate. The electronic signal is read out on a series of data lines as the switches in each row of the array are activated. In another system, the light is coupled through demagnifying fiberoptic tapers to a CCD readout. A mosaic of  $3 \times 4$  detector modules is formed (Figure 10.21b) to obtain a detector large enough to cover the breast [Cheung, 1998]. A third system also uses fiberoptic coupling of CsI to CCDs; however, the detector is in a slot configuration and is scanned beneath the breast in synchrony with a fan beam of x-rays to acquire the transmitted signal (Figure 10.21c). The fourth system employs a plate formed of a photostimulable phosphor material. When exposed to x-rays, traps in the phosphor are filled with electrons, the number being related to x-ray intensity. The plate is placed in a reader device and scanned with a red HeNe laser beam which stimulates the traps to release the electrons. The transition of these electrons through energy levels in the phosphor crystal result in the formation of blue light, which is measured as a function of the laser position on the plate to form the image signal.

**FIGURE 10.21** (a) Small-format detector system for biopsy imaging, (b) full-breast detector incorporating 12 detector modules, (c) slot detector for a full-breast scanning digital mammography system.

Other materials in which x-ray energy is directly converted to charge are under development for digital mammography. These materials include lead iodide, amorphous selenium, zinc cadmium telluride, and thallium bromide. A review of the current status of digital mammography is given in [Yaffe, 1994; Pisano, 1998] and of detectors for digital x-ray imaging in Yaffe [1997].

### 10.3.7 Summary

Mammography is a technically demanding imaging procedure which can help reduce mortality from breast cancer. To be successful at this purpose, both the technology and technique used for imaging must be optimized. This requires careful system design and attention to quality control procedures. Imaging systems for mammography are still evolving and, in the future, are likely to make greater use of digital acquisition and display methods.

### Defining Terms

**Conversion efficiency:** The efficiency of converting the energy from x-rays absorbed in a phosphor material into that of emitted light quanta.

**Fibroglandular tissue:** A mixture of tissues within the breast composed of the functional glandular tissue and the fibrous supporting structures.

**Focal spot:** The area of the anode of an x-ray tube from which the useful beam of x-rays is emitted. Also known as the target.

**Grid:** A device consisting of evenly spaced lead strips which functions like a venetian blind in preferentially allowing x-rays traveling directly from the focal spot without interaction in the patient to pass through, while those whose direction has been diverted by scattering in the patient strike the slats of the grid and are rejected. Grids improve the contrast of radiographic images at the price of increased dose to the patient.

**Image receptor:** A device that records the distribution of x-rays to form an image. In mammography, the image receptor is generally composed of a light-tight cassette containing a fluorescent screen, which absorbs x-rays and produces light, coupled to a sheet of photographic film.

**Quantum efficiency:** The fraction of incident x-rays which interact with a detector or image receptor.

**Screening:** Examination of asymptomatic individuals to detect disease.

**Survival:** An epidemiological term giving the fraction of individuals diagnosed with a given disease alive at a specified time after diagnosis, for example, "10-year survival".

### 11.1 Instrumentation

---

*Ian A. Cunningham*

The development of **computed tomography (CT)** in the early 1970s revolutionized medical radiology. For the first time, physicians were able to obtain high-quality tomographic (cross-sectional) images of internal structures of the body. Over the next ten years, 18 manufacturers competed for the exploding world CT market. Technical sophistication increased dramatically, and even today, CT continues to mature, with new capabilities being researched and developed.

Computed tomographic images are reconstructed from a large number of measurements of **x-ray transmission** through the patient (called **projection data**). The resulting images are tomographic “maps” of the x-ray linear **attenuation** coefficient. The mathematical methods used to **reconstruct** CT images from projection data are discussed in the next section. In this section, the hardware and instrumentation in a modern scanner are described.

The first practical CT instrument was developed in 1971 by **Dr. G.N. Hounsfield** in England and was used to image the brain [Hounsfield, 1980]. The projection data were acquired in approximately 5 min, and the tomographic image was reconstructed in approximately 20 min. Since then, CT technology has developed dramatically, and CT has become a standard imaging procedure for virtually all parts of the body in thousands of facilities throughout the world. Projection data are typically acquired in approximately 1 sec, and the image is reconstructed in 3 to 5 sec. One special-purpose scanner described below acquires the projection data for one tomographic image in 50 msec. A typical modern CT scanner is shown in Figure 11.1, and typical CT images are shown in Figure 11.2.

**FIGURE 11.1** Schematic drawing of a typical CT scanner installation, consisting of (1) control console, (2) gantry stand, (3) patient table, (4) head holder, and (5) laser imager. (Courtesy of Picker International, Inc.)

**FIGURE 11.2** Typical CT images of (a) brain, (b) head showing orbits, (c) chest showing lungs, and (d) abdomen.

The fundamental task of CT systems is to make an extremely large number (approximately 500,000) of highly accurate measurements of x-ray transmission through the patient in a precisely controlled geometry. A basic system generally consists of a **gantry**, a patient table, a **control console**, and a computer. The gantry contains the **x-ray source**, **x-ray detectors**, and the **data-acquisition system (DAS)**.

**11.1.1 Data-Acquisition Geometries**

Projection data may be acquired in one of several possible geometries described below, based on the scanning configuration, scanning motions, and detector arrangement. The evolution of these geometries

FIGURE 11.3 Four generations of CT scanners illustrating the parallel- and fan-beam geometries. (Taken from Robb R.A. 1982, *CRC Crit. Rev. Biomed. Eng.* 7: 265.)

is described in terms of “generations,” as illustrated in Figure 11.3, and reflects the historical development [Newton and Potts, 1981; Seeram, 1994]. Current CT scanners use either third-, fourth-, or fifth-generation geometries, each having their own pros and cons.

**11.1.1.1 First Generation: Parallel-Beam Geometry**

Parallel-beam geometry is the simplest technically and the easiest with which to understand the important CT principles. Multiple measurements of x-ray transmission are obtained using a single highly collimated x-ray **pencil beam** and detector. The beam is translated in a linear motion across the patient to obtain a projection profile. The source and detector are then rotated about the patient isocenter by approximately 1 degree, and another projection profile is obtained. This translate-rotate scanning motion is repeated until the source and detector have been rotated by 180 degrees. The highly collimated beam provides excellent rejection of radiation scattered in the patient; however, the complex scanning motion results in long (approximately 5-min) **scan times**. This geometry was used by Hounsfield in his original experiments [Hounsfield, 1980] but is not used in modern scanners.

**11.1.1.2 Second Generation: Fan Beam, Multiple Detectors**

Scan times were reduced to approximately 30 sec with the use of a **fan beam** of x-rays and a linear **detector array**. A translate-rotate scanning motion was still employed; however, a larger rotate increment could be used, which resulted in shorter scan times. The reconstruction algorithms are slightly more complicated than those for first-generation algorithms because they must handle fan-beam projection data.

### 11.1.1.3 Third Generation: Fan Beam, Rotating Detectors

Third-generation scanners were introduced in 1976. A fan beam of x-rays is rotated 360 degrees around the isocenter. No translation motion is used; however, the fan beam must be wide enough to completely contain the patient. A curved detector array consisting of several hundred independent detectors is mechanically coupled to the x-ray source, and both rotate together. As a result, these rotate-only motions acquire projection data for a single image in as little as 1 sec. Third-generation designs have the advantage that thin tungsten septa can be placed between each detector in the array and focused on the x-ray source to reject **scattered radiation**.

### 11.1.1.4 Fourth Generation: Fan Beam, Fixed Detectors

In a fourth-generation scanner, the x-ray source and fan beam rotate about the isocenter, while the detector array remains stationary. The detector array consists of 600 to 4800 (depending on the manufacturer) independent detectors in a circle that completely surrounds the patient. Scan times are similar to those of third-generation scanners. The detectors are no longer coupled to the x-ray source and hence cannot make use of **focused septa** to reject scattered radiation. However, detectors are calibrated twice during each rotation of the x-ray source, providing a self-calibrating system. Third-generation systems are calibrated only once every few hours.

Two detector geometries are currently used for fourth-generation systems (1) a rotating x-ray source inside a fixed detector array and (2) a rotating x-ray source outside a rotating detector array. Figure 11.4 shows the major components in the gantry of a typical fourth-generation system using a fixed-detector array. Both third- and fourth-generation systems are commercially available, and both have been highly successful clinically. Neither can be considered an overall superior design.

### 11.1.1.5 Fifth Generation: Scanning Electron Beam

Fifth-generation scanners are unique in that the x-ray source becomes an integral part of the system design. The detector array remains stationary, while a high-energy electron beam is electronically swept along a semicircular tungsten strip **anode**, as illustrated in Figure 11.5. X-rays are produced at the point where the electron beam hits the anode, resulting in a source of x-rays that rotates about the patient with no moving parts [Boyd et al., 1979]. Projection data can be acquired in approximately 50 msec, which is fast enough to image the beating heart without significant motion artifacts [Boyd and Lipton, 1983].

An alternative fifth-generation design, called the dynamic spatial reconstructor (DSR) scanner, is in use at the Mayo Clinic [Ritman, 1980, 1990]. This machine is a research prototype and is not available commercially. It consists of 14 x-ray tubes, scintillation screens, and video cameras. **Volume CT** images can be produced in as little as 10 msec.

### 11.1.1.6 Spiral/Helical Scanning

The requirement for faster scan times, and in particular for fast multiple scans for **three-dimensional imaging**, has resulted in the development of spiral (**helical**) scanning systems [Kalendar et al., 1990]. Both third- and fourth-generation systems achieve this using self-lubricating slip-ring technology (Figure 11.6) to make the electrical connections with rotating components. This removes the need for power and signal cables which would otherwise have to be rewound between scans and allows for a continuous rotating motion of the x-ray fan beam. Multiple images are acquired while the patient is translated through the gantry in a smooth continuous motion rather than stopping for each image. Projection data for multiple images covering a volume of the patient can be acquired in a single breath hold at rates of approximately one **slice** per second. The reconstruction algorithms are more sophisticated because they must accommodate the spiral or helical path traced by the x-ray source around the patient, as illustrated in Figure 11.7.

## 11.1.2 X-Ray System

The x-ray system consists of the x-ray source, detectors, and a data-acquisition system.

FIGURE 11.4 The major internal components of a fourth-generation CT gantry are shown in a photograph with the gantry cover removed (upper) and identified in the line drawing (lower). (Courtesy of Picker International, Inc.)

11.1.2.1 X-Ray Source

With the exception of one fifth-generation system described above, all CT scanners use bremsstrahlung x-ray tubes as the source of radiation. These tubes are typical of those used in diagnostic imaging and produce x-rays by accelerating a beam of electrons onto a target anode. The anode area from which x-rays are emitted, projected along the direction of the beam, is called the **focal spot**. Most systems have two possible focal spot sizes, approximately  $0.5 \times 1.5$  mm and  $1.0 \times 2.5$  mm. A collimator assembly is used to control the width of the fan beam between 1.0 and 10 mm, which in turn controls the width of the imaged slice.

The power requirements of these tubes are typically 120 kV at 200 to 500 mA, producing x-rays with an energy spectrum ranging between approximately 30 and 120 keV. All modern systems use high-frequency generators, typically operating between 5 and 50 kHz [Brunnett et al., 1990]. Some spiral systems use a

**FIGURE 11.5** Schematic illustration of a fifth-generation ultrafast CT system. Image data are acquired in as little as 50 msec, as an electron beam is swept over the strip anode electronically. (Courtesy of Imatron, Inc.)

**FIGURE 11.6** Photograph of the slip rings used to pass power and control signals to the rotating gantry. (Courtesy of Picker International, Inc.)

stationary generator in the gantry, requiring high-voltage (120-kV) slip rings, while others use a rotating generator with lower-voltage (480-V) slip rings. Production of x-rays in bremsstrahlung tubes is an inefficient process, and hence most of the power delivered to the tubes results in heating of the anode. A heat exchanger on the rotating gantry is used to cool the tube. **Spiral scanning**, in particular, places heavy demands on the heat-storage capacity and cooling rate of the x-ray tube.

**FIGURE 11.7** Spiral scanning causes the focal spot to follow a spiral path around the patient as indicated. (Courtesy of Picker International, Inc.)

The intensity of the x-ray beam is attenuated by **absorption** and scattering processes as it passes through the patient. The degree of attenuation depends on the energy spectrum of the x-rays as well as on the average atomic number and mass density of the patient tissues. The transmitted intensity is given by

$$I_t = I_0 e^{-\int_0^L \mu(x) dx} \tag{11.1}$$

where  $I_0$  and  $I_t$  are the incident and transmitted beam intensities, respectively;  $L$  is the length of the x-ray path; and  $m(x)$  is the **x-ray linear attenuation coefficient**, which varies with tissue type and hence is a function of the distance  $x$  through the patient. The integral of the attenuation coefficient is therefore given by

$$\int_0^L \mu(x) dx = -\frac{1}{L} \ln(I_t/I_0) \tag{11.2}$$

The reconstruction algorithm requires measurements of this integral along many paths in the fan beam at each of many angles about the isocenter. The value of  $L$  is known, and  $I_0$  is determined by a system calibration. Hence values of the integral along each path can be determined from measurements of  $I_t$ .

### 11.1.2.2 X-Ray Detectors

X-ray detectors used in CT systems must (a) have a high overall efficiency to minimize the patient radiation dose, have a large dynamic range, (b) be very stable with time, and (c) be insensitive to temperature variations within the gantry. Three important factors contributing to the detector efficiency are geometric efficiency, quantum (also called capture) efficiency, and conversion efficiency [Villafanaet et al., 1987]. Geometric efficiency refers to the area of the detectors sensitive to radiation as a fraction of the total exposed area. Thin septa between detector elements to remove scattered radiation, or other insensitive regions, will degrade this value. Quantum efficiency refers to the fraction of incident x-rays on the detector that are absorbed and contribute to the measured signal. Conversion efficiency refers to the ability to accurately convert the absorbed x-ray signal into an electrical signal (but is not the same as the energy conversion efficiency). Overall efficiency is the product of the three, and it generally lies between 0.45 and 0.85. A value of less than 1 indicates a nonideal detector system and results in a required increase in patient radiation

**FIGURE 11.8** (a) A solid-state detector consists of a scintillating crystal and photodiode combination. (b) Many such detectors are placed side by side to form a detector array that may contain up to 4800 detectors.

**FIGURE 11.9** Gas ionization detector arrays consist of high-pressure gas in multiple chambers separated by thin septa. A voltage is applied between alternating septa. The septa also act as electrodes and collect the ions created by the radiation, converting them into an electrical signal.

dose if image quality is to be maintained. The term dose efficiency sometimes has been used to indicate overall efficiency.

Modern commercial systems use one of two detector types: solid-state or gas ionization detectors.

*Solid-State Detectors.* Solid-state detectors consist of an array of scintillating crystals and photodiodes, as illustrated in Figure 11.8. The scintillators generally are either cadmium tungstate ( $CdWO_4$ ) or a ceramic material made of rare earth oxides, although previous scanners have used bismuth germanate crystals with photomultiplier tubes. Solid-state detectors generally have very high quantum and conversion efficiencies and a large dynamic range.

*Gas Ionization Detectors.* Gas ionization detectors, as illustrated in Figure 11.9, consist of an array of chambers containing compressed gas (usually xenon at up to 30 atm pressure). A high voltage is applied to tungsten septa between chambers to collect ions produced by the radiation. These detectors have excellent stability and a large dynamic range; however, they generally have a lower quantum efficiency than solid-state detectors.

**11.1.2.3 Data-Acquisition System**

The transmitted fraction  $I_t/I_o$  in Equation 11.2 through an obese patient can be less than 10 to 4. Thus it is the task of the data-acquisition system (DAS) to accurately measure  $I_t$  over a dynamic

**FIGURE 11.10** The data-acquisition system converts the electrical signal produced by each detector to a digital value for the computer.

range of more than 104, encode the results into digital values, and transmit the values to the system computer for reconstruction. Some manufacturers use the approach illustrated in Figure 11.10, consisting of precision preamplifiers, current-to-voltage converters, analog integrators, multiplexers, and analog-to-digital converters. Alternatively, some manufacturers use the preamplifier to control a synchronous voltage-to-frequency converter (SVFC), replacing the need for the integrators, multiplexers, and analog-to-digital converters [Brunnett et al., 1990]. The logarithmic conversion required in Equation 11.2 is performed with either an analog logarithmic amplifier or a digital lookup table, depending on the manufacturer.

Sustained data transfer rates to the computer are as high as 10 Mbytes/sec for some scanners. This can be accomplished with a direct connection for systems having a fixed detector array. However, third-generation slip-ring systems must use more sophisticated techniques. At least one manufacturer uses optical transmitters on the rotating gantry to send data to fixed optical receivers [Siemens, 1989].

#### 11.1.2.4 Computer System

Various computer systems are used by manufacturers to control system hardware, acquire the projection data, and reconstruct, display, and manipulate the tomographic images. A typical system is illustrated in Figure 11.11, which uses 12 independent processors connected by a 40-Mbyte/sec multibus. Multiple custom array processors are used to achieve a combined computational speed of 200 MFLOPS (million floating-point operations per second) and a reconstruction time of approximately 5 sec to produce an image on a  $1024 \times 1024$  pixel display. A simplified UNIX operating system is used to provide a multitasking, multiuser environment to coordinate tasks.

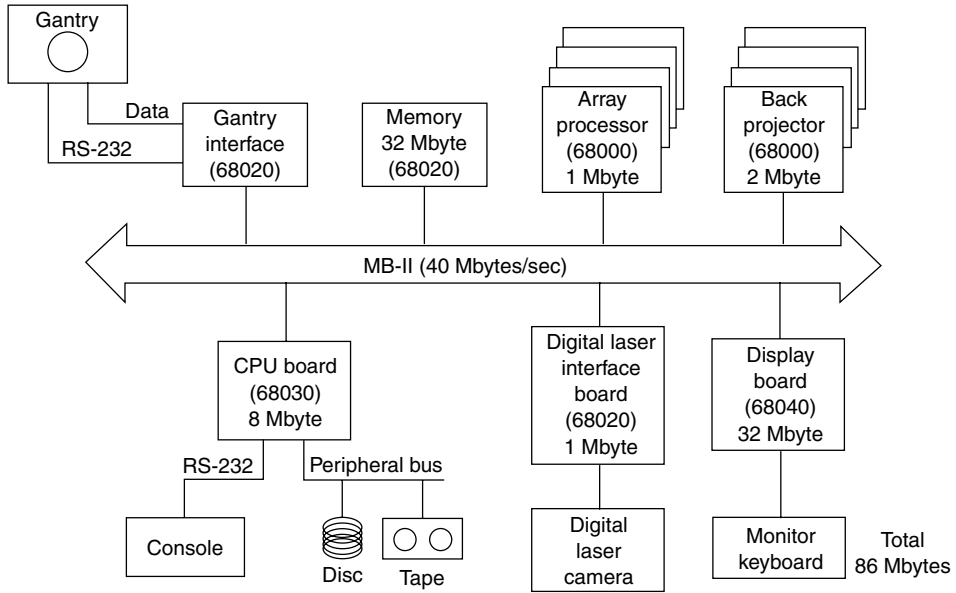

### 11.1.3 Patient Dose Considerations

The patient dose resulting from CT examinations is generally specified in terms of the CT dose index (CTDI) [Felmlee et al., 1989; Rothenberg and Pentlow, 1992], which includes the dose contribution from radiation scattered from nearby slices. A summary of CTDI values, as specified by four manufacturers, is given in Table 11.1.

### 11.1.4 Summary

Computed tomography revolutionized medical radiology in the early 1970s. Since that time, CT technology has developed dramatically, taking advantage of developments in computer hardware and detector technology. Modern systems acquire the projection data required for one tomographic image in approximately 1 sec and present the reconstructed image on a  $1024 \times 1024$  matrix display within a few seconds. The images are high-quality tomographic “maps” of the x-ray linear attenuation coefficient of the patient tissues.

**FIGURE 11.11** The computer system controls the gantry motions, acquires the x-ray transmission measurements, and reconstructs the final image. The system shown here uses 1,268,000-family CPUs. (Courtesy of Picker International, Inc.)

**TABLE 11.1** Summary of the CT Dose Index (CTDI) Values at Two Positions (Center of the Patient and Near the Skin) as Specified by Four CT Manufacturers for Standard Head and Body Scans

Manufacturer	Detector	CTDI, center CTDI, skin				
		kVp	mA	Scan time (sec)	(mGy)	(mGy)
A, head	Xenon	120	170	2	50	48
A, body	Xenon	120	170	2	14	25
A, head	Solid state	120	170	2	40	40
A, body	Solid state	120	170	2	11	20
B, head	Solid state	130	80	2	37	41
B, body	Solid state	130	80	2	15	34
C, head	Solid state	120	500	2	39	50
C, body	Solid state	120	290	1	12	28
D, head	Solid state	120	200	2	78	78
D, body	Solid state	120	200	2	9	16

### Defining Terms

**Absorption:** Some of the incident x-ray energy is absorbed in patient tissues and hence does not contribute to the transmitted beam.

**Anode:** A tungsten bombarded by a beam of electrons to produce x-rays. In all but one fifth-generation system, the anode rotates to distribute the resulting heat around the perimeter. The anode heat-storage capacity and maximum cooling rate often limit the maximum scanning rates of CT systems.

**Attenuation:** The total decrease in the intensity of the primary x-ray beam as it passes through the patient, resulting from both scatter and absorption processes. It is characterized by the linear attenuation coefficient.

**Computed tomography (CT):** A computerized method of producing x-ray tomographic images. Previous names for the same thing include computerized tomographic imaging, computerized axial tomography (CAT), computer-assisted tomography (CAT), and reconstructive tomography (RT).

**Control console:** The control console is used by the CT operator to control the scanning operations, image reconstruction, and image display.

**Cormack, Dr. Allan MacLeod:** A physicist who developed mathematical techniques required in the reconstruction of tomographic images. Dr. Cormack shared the Nobel Prize in Medicine and Physiology with Dr. G.N. Hounsfield in 1979 [Cormack, 1980].

**Data-acquisition system (DAS):** Interfaces the x-ray detectors to the system computer and may consist of a preamplifier, integrator, multiplexer, logarithmic amplifier, and analog-to-digital converter.

**Detector array:** An array of individual detector elements. The number of detector elements varies between a few hundred and 4800, depending on the acquisition geometry and manufacturer. Each detector element functions independently of the others.

**Fan beam:** The x-ray beam is generated at the focal spot and so diverges as it passes through the patient to the detector array. The thickness of the beam is generally selectable between 1.0 and 10 mm and defines the slice thickness.

**Focal spot:** The region of the anode where x-rays are generated.

**Focused septa:** Thin metal plates between detector elements which are aligned with the focal spot so that the primary beam passes unattenuated to the detector elements, while scattered x-rays which normally travel in an altered direction are blocked.

**Gantry:** The largest component of the CT installation, containing the x-ray tube, collimators, detector array, DAS, other control electronics, and the mechanical components required for the scanning motions.

**Helical scanning:** The scanning motions in which the x-ray tube rotates continuously around the patient while the patient is continuously translated through the fan beam. The focal spot therefore traces a helix around the patient. Projection data are obtained which allow the reconstruction of multiple contiguous images. This operation is sometimes called spiral, volume, or three-dimensional CT scanning.

**Hounsfield, Dr. Godfrey Newbold:** An engineer who developed the first practical CT instrument in 1971. Dr. Hounsfield received the McRobert Award in 1972 and shared the Nobel Prize in Medicine and Physiology with Dr. A.M. Cormack in 1979 for this invention [Hounsfield, 1980].

**Image plane:** The plane through the patient that is imaged. In practice, this plane (also called a slice) has a selectable thickness between 1.0 and 10 mm centered on the image plane.

**Pencil beam:** A narrow, well-collimated beam of x-rays.

**Projection data:** The set of transmission measurements used to reconstruct the image.

**Reconstruct:** The mathematical operation of generating the tomographic image from the projection data.

**Scan time:** The time required to acquire the projection data for one image, typically 1.0 sec.

**Scattered radiation:** Radiation that is removed from the primary beam by a scattering process. This radiation is not absorbed but continues along a path in an altered direction.

**Slice:** See Image plane.

**Spiral scanning:** See Helical scanning.

**Three-dimensional imaging:** See Helical scanning.

**Tomography:** A technique of imaging a cross-sectional slice.

**Volume CT:** See Helical scanning.

**X-ray detector:** A device that absorbs radiation and converts some or all of the absorbed energy into a small electrical signal.

**X-ray linear attenuation coefficient  $m$ :** Expresses the relative rate of attenuation of a radiation beam as it passes through a material. The value of  $m$  depends on the density and atomic number of the material and on the x-ray energy. The units of  $m$  are  $\text{cm}^{-1}$ .

**X-ray source:** The device that generates the x-ray beam. All CT scanners are rotating-anode bremsstrahlung x-ray tubes except one-fifth generation system, which uses a unique scanned electron beam and a strip anode.

**X-ray transmission:** The fraction of the x-ray beam intensity that is transmitted through the patient without being scattered or absorbed. It is equal to  $I_t/I_o$  in Equation 11.2, can be determined by measuring the beam intensity both with ( $I_t$ ) and without ( $I_o$ ) the patient present, and is expressed as a fraction. As a rule of thumb,  $n^2$  independent transmission measurements are required to reconstruct an image with an  $n \times n$  sized pixel matrix.

## Further Information

A recent summary of CT instrumentation and concepts is given by E. Seeram in *Computed Tomography: Physical Principles, Clinical Applications and Quality Control*. The author summarizes CT from the perspective of the nonmedical, nonspecialist user. A summary of average CT patient doses is described by Rothenberg and Pentlow [1992] in *Radiation Dose in CT*. Research papers on both fundamental and practical aspects of CT physics and instrumentation are published in numerous journals, including *Medical Physics*, *Physics in Medicine and Biology*, *Journal of Computer Assisted Tomography*, *Radiology*, *British Journal of Radiology*, and the IEEE Press. A comparison of technical specifications of CT systems provided by the manufacturers is available from ECRI to help orient the new purchaser in a selection process.

Their Product Comparison System includes a table of basic specifications for all the major international manufactures.

## 11.2 Reconstruction Principles

---

### *Philip F. Judy*

Computed tomography (CT) is a two-step process (1) the transmission of an x-ray beam is measured through all possible straight-line paths as in a plane of an object, and (2) the attenuation of an x-ray beam is estimated at points in the object. Initially, the transmission measurements will be assumed to be the results of an experiment performed with a narrow monoenergetic beam of x-rays that are confined to a plane. The designs of devices that attempt to realize these measurements are described in the preceding section. One formal consequence of these assumptions is that the logarithmic transformation of the measured x-ray intensity is proportional to the line integral of attenuation coefficients. In order to satisfy this assumption, computer processing procedures on the measurements of x-ray intensity are necessary even before image reconstruction is performed. These linearization procedures will be reviewed after background.

Both analytical and iterative estimations of linear x-ray attenuation have been used for transmission CT reconstruction. Iterative procedures are of historic interest because an iterative reconstruction procedure was used in the first commercially successful CT scanner [EMI, Mark I, Hounsfield, 1973]. They also permit easy incorporation of physical processes that cause deviations from the linearity. Their practical usefulness is limited. The first EMI scanner required 20 min to finish its reconstruction. Using the identical hardware and employing an analytical calculation, the estimation of attenuation values was performed during the 4.5-min data acquisition and was made on a  $160 \times 160$  matrix. The original iterative procedure reconstructed the attenuation values on an  $80 \times 80$  matrix and consequently failed to exploit all the spatial information inherent in transmission data.

Analytical estimation, or direct reconstruction, uses a numerical approximation of the inverse Radon transform [Radon, 1917]. The direct reconstruction technique (convolution-backprojection) presently used in x-ray CT was initially applied in other areas such as radio astronomy [Bracewell and Riddle, 1967] and electron microscopy [Crowther et al., 1970; Ramachandran and Lakshminarayana, 1971]. These investigations demonstrated that the reconstructions from the discrete spatial sampling of band-limited data led to full recovery of the cross-sectional attenuation. The random variation (noise) in x-ray transmission measurements may not be bandlimited. Subsequent investigators [Herman and Rowland, 1973; Shepp and Logan, 1974; Chesler and Riederer, 1975] have suggested various bandlimiting windows that reduce the propagation and amplification of noise by the reconstruction. These issues have been investigated by simulation, and investigators continue to pursue these issues using a computer phantom [e.g., Guedon and Bizais, 1994, and references therein] described by Shepp and Logan. The subsequent investigations of the details of choice of reconstruction parameters has had limited practical impact because real variation of transmission data is bandlimited by the finite size of the focal spot and radiation detector, a straightforward design question, and because random variation of the transmission tends to be uncorrelated. Consequently, the classic procedures suffice.

### 11.2.1 Image Processing: Artifact and Reconstruction Error

An artifact is a reconstruction defect that is obviously visible in the image. The classification of an image feature as an artifact involves some visual criterion. The effect must produce an image feature that is greater than the random variation in image caused by the intrinsic variation in transmission measurements. An artifact not recognized by the physician observer as an artifact may be reported as a lesion. Such false-positive reports could lead to an unnecessary medical procedure, for example, surgery to remove an imaginary tumor. A reconstruction error is a deviation of the reconstruction value from its expected value. Reconstruction errors are significant if the application involves a quantitative measurement, not a common medical application. The reconstruction errors are characterized by identical material at different

points in the object leading to different reconstructed attenuation values in the image which are not visible in the medical image.

Investigators have used computer simulation to investigate artifact [Herman, 1980] because image noise limits the visibility of their visibility. One important issue investigated was required spatial sampling of transmission slice plane [Crawford and Kak, 1979; Parker et al., 1982]. These simulations provided a useful guideline in design. In practice, these aliasing artifacts are overwhelmed by random noise, and designers tend to oversample in the slice plane. A second issue that was understood by computer simulation was the partial volume artifact [Glover and Pelc, 1980]. This artifact would occur even for monenergetic beams and finite beam size, particularly in the axial dimension. The axial dimension of the beams tend to be greater (about 10 mm) than their dimensions in the slice plane (about 1 mm). The artifact is created when the variation of transmission within the beam varies considerably, and the exponential variation within the beam is summed by the radiation detector. The logarithm transformation of the detected signal produces a nonlinear effect that is propagated throughout the image by the reconstruction process. Simulation was useful in demonstrating that isolated features in the same cross-section act together to produce streak artifacts. Simulations have been useful to illustrate the effects of patient motion during the data-acquisition streaks off high-contrast objects.

### 11.2.2 Projection Data to Image: Calibrations

Processing of transmission data is necessary to obtain high-quality images. In general, optimization of the projection data will optimize the reconstructed image. Reconstruction is a process that removes the spatial correlation of attenuation effects in the transmitted image by taking advantage of completely sampling the possible transmissions. Two distinct calibrations are required: registration of beams with the reconstruction matrix and linearization of the measured signal.

Without loss of generalization, a projection will be considered a set of transmissions made along parallel lines in the slice plane of the CT scanner. Without loss of generalization means that essential aspects of all calibration and reconstruction procedures required for fan-beam geometries are captured by the calibration and reconstruction procedures described for parallel projections. One line of each projection is assumed to pass through the center of rotation of data collection. Shepp et al. [1979] showed that errors in the assignment of that center-of-rotation point in the projections could lead to considerable distinctive artifacts and that small errors (0.05 mm) would produce these effects. The consequences of these errors have been generalized to fan-beam collection schemes, and images reconstructed from 180-degree projection sets were compared with images reconstructed from 360-degree data sets [Kijewski and Judy, 1983]. A simple misregistration of the center of rotation was found to produce blurring of image without the artifact. These differences may explain the empirical observation that most commercial CT scanners collect a full 360-degree data set even though 180 degree of data will suffice.

The data-acquisition scheme that was designed to overcome the limited sampling inherent in third-generation fan-beam systems by shifting detectors a quarter sampling distance while opposite 180-degree projection is measured, has particularly stringent registration requirements. Also, the fourth-generation scanner does not link the motion of the x-ray tube and the detector; consequently, the center of rotation is determined as part of a calibration procedure, and unsystematic effects lead to artifacts that mimic noise besides blurring the image.

Misregistration artifacts also can be mitigated by feathering. This procedure requires collection of redundant projection data at the end of the scan. A single data set is produced by linearly weighting the redundant data at the beginning and end of the data collection [Parker et al., 1982]. These procedures have been useful in reducing artifacts from gated data collections [Moore et al., 1987].

The other processing necessary before reconstruction of project data is linearization. The formal requirement for reconstruction is that the line integrals of some variable be available; this is the variable that ultimately is reconstructed. The logarithm of x-ray transmission approximates this requirement. There are physical effects in real x-ray transmissions that cause deviations from this assumption. X-ray

beams of sufficient intensity are composed of photons of different energies. Some photons in the beam interact with objects and are scattered rather than absorbed. The spectrum of x-ray photons of different attenuation coefficients means the logarithm of the transmission measurement will not be proportional to the line integral of the attenuation coefficient along that path, because an attenuation coefficient cannot even be defined. An effective attenuation coefficient can only be defined uniquely for a spectrum for a small mass of material that alters that intensity. It has to be small enough not to alter the spectrum [McCullough, 1979].

A straightforward approach to this nonunique attenuation coefficient error, called hardening, is to assume that the energy dependence of the attenuation coefficient is constant and that differences in attenuation are related to a generalized density factor that multiplies the spectral dependence of attenuation. The transmission of an x-ray beam then can be estimated for a standard material, typically water, as a function of thickness. This assumption is that attenuations of materials in the object, the human body, differ because specific gravities of the materials differ. Direct measurements of the transmission of an actual x-ray beam may provide initial estimates that can be parameterized. The inverse of this function provides the projection variable that is reconstructed. The parameters of the function are usually modified as part of a calibration to make the CT image of a uniform water phantom flat.

Such a calibration procedure does not deal completely with the hardening effects. The spectral dependence of bone differs considerably from that of water. This is particularly critical in imaging of the brain, which is contained within the skull. Without additional correction, the attenuation values of brain are lower in the center than near the skull.

The detection of scattered energy means that the reconstructed attenuation coefficient will differ from the attenuation coefficient estimated with careful narrow-beam measurements. The x-rays appear more penetrating because scattered x-rays are detected. The zero-ordered scatter, a decrease in the attenuation coefficient by some constant amount, is dealt with automatically by the calibration that treats hardening. First-order scattering leads to a widening of the x-ray beam and can be dealt with by a modification of the reconstruction kernel.

### 11.2.3 Projection Data to Image: Reconstruction

The impact of CT created considerable interest in the formal aspects of reconstruction. There are many detailed descriptions of direct reconstruction procedures. Some are presented in textbooks used in graduate courses for medical imaging [Barrett and Swindell, 1981; Cho et al., 1993]. Herman [1980] published a textbook that was based on a two-semester course that dealt exclusively with reconstruction principles, demonstrating the reconstruction principles with simulation.

The standard reconstruction method is called convolution-backprojection. The first step in the procedure is to convolve the projection, a set of transmissions made along parallel lines in the slice plane, with a reconstruction kernel derived from the inverse Radon transform. The choice of kernel is dictated by bandlimiting issues [Herman and Rowland, 1973; Shepp and Logan, 1974; Chesler and Riederer, 1975]. It can be modified to deal with the physical aperture of the CT system [Bracewell, 1977], which might include the effects of scatter. The convolved projection is then backprojected onto a two-dimensional image matrix. Backprojection is the opposite of projection; the value of the projection is added to each point along the line of the projection. This procedure makes sense in the continuous description, but in the discrete world of the computer, the summation is done over the image matrix.

Consider a point of the image matrix; very few, possibly no lines of the discrete projection data intersect the point. Consequently, to estimate the projection value to be added to that point, the procedure must interpolate between two values of sampled convolve projection. The linear interpolation scheme is a significant improvement over nearest project nearest to the point. More complex schemes get confounded with choices of reconstruction kernel, which are designed to accomplish standard image processing in the image, for example, edge enhancement.

Scanners have been developed to acquire a three-dimensional set of projection data [Kalender et al., 1990]. The motion of the source defines a spiral motion relative to the patient. The spiral motion defines

an axis. Consequently, only one projection is available for reconstruction of the attenuation values in the plane. This is the back-projection problem just discussed; no correct projection value is available from the discrete projection data set. The solution is identical: a projection value is interpolated from the existing projection values to estimate the necessary projections for each plane to be reconstructed. This procedure has the advantage that overlapping slices can be reconstructed without additional exposure, and this eliminates the risk that a small lesion will be missed because it straddles adjacent slices. This data-collection scheme is possible because systems that continuously rotate have been developed. The spiral scan motion is realized by moving the patient through the gantry. Spiral CT scanners have made possible the acquisition of an entire data set in a single breath hold.

### 12.1 Acquisition and Processing

---

*Steven Conolly, Albert Macovski, and John Pauly*

Magnetic resonance imaging (MRI) is a clinically important medical imaging modality due to its exceptional soft-tissue contrast. MRI was invented in the early 1970s [1]. The first commercial scanners appeared about 10 years later. Noninvasive MRI studies are now supplanting many conventional invasive procedures. A 1990 study [2] found that the principal applications for MRI are examinations of the head (40%), spine (33%), bone and joints (17%), and the body (10%). The percentage of bone and joint studies was growing in 1990.

Although typical imaging studies range from 1 to 10 min, new fast imaging techniques acquire images in less than 50 msec. MRI research involves fundamental tradeoffs between resolution, imaging time,

and signal-to-noise ratio (SNR). It also depends heavily on both gradient and receiver coil hardware innovations.

In this section we provide a brief synopsis of basic nuclear magnetic resonance (NMR) physics. We then derive the  $k$ -**space** analysis of MRI, which interprets the received signal as a scan of the Fourier transform of the image. This powerful formalism is used to analyze the most important imaging sequences. Finally, we discuss the fundamental contrast mechanisms for MRI.

### 12.1.1 Fundamentals of MRI

Magnetic resonance imaging exploits the existence of induced nuclear magnetism in the patient. Materials with an odd number of protons or neutrons possess a weak but observable nuclear magnetic moment. Most commonly protons ( $^1\text{H}$ ) are imaged, although carbon ( $^{13}\text{C}$ ), phosphorous ( $^{31}\text{P}$ ), sodium ( $^{23}\text{Na}$ ), and fluorine ( $^{19}\text{F}$ ) are also of significant interest. The nuclear moments are normally randomly oriented, but they align when placed in a strong magnetic field. Typical field strengths for imaging range between 0.2 and 1.5 T, although spectroscopic and functional imaging work is often performed with higher field strengths. The nuclear **magnetization** is very weak; the ratio of the induced magnetization to the applied fields is only  $4 \times 10^{-9}$ . The collection of nuclear moments is often referred to as magnetization or **spins**.

The static nuclear moment is far too weak to be measured when it is aligned with the strong static magnetic field. Physicists in the 1940s developed resonance techniques that permit this weak moment to be measured. The key idea is to measure the moment while it oscillates in a plane perpendicular to the static field [3,4]. First one must tip the moment away from the static field. When perpendicular to the static field, the moment feels a torque proportional to the strength of the static magnetic field. The torque always points perpendicular to the magnetization and causes the spins to oscillate or precess in a plane perpendicular to the static field. The frequency of the rotation  $\omega_0$  is proportional to the field:

$$\omega_0 = -\gamma B_0$$

where  $\gamma$ , the **gyromagnetic ratio**, is a constant specific to the nucleus, and  $B_0$  is the magnetic field strength. The direction of  $B_0$  defines the  $z$ -axis. The **precession** frequency is called the **Larmor frequency**. The negative sign indicates the direction of the precession.

Since the precessing moments constitute a time-varying flux, they produce a measurable voltage in a loop antenna arranged to receive the  $x$  and  $y$  components of induction. It is remarkable that in MRI we are able to directly measure induction from the precessing nuclear moments of water protons.

Recall that to observe this precession, we first need to tip the magnetization away from the static field. This is accomplished with a weak rotating radiofrequency (RF) field. It can be shown that a rotating RF field introduces a fictitious field in the  $z$  direction of strength  $\omega/\gamma$ . By tuning the frequency of the RF field to  $\omega_0$ , we effectively delete the  $B_0$  field. The RF slowly nutates the magnetization away from the  $z$ -axis. The Larmor relation still holds in this “rotating frame,” so the frequency of the nutation is  $\gamma B_1$ , where  $B_1$  is the amplitude of the RF field. Since the coils receive  $x$  and  $y$  (transverse) components of induction, the signal is maximized by tipping the spins completely into the transverse plane. This is accomplished by a  $\pi/2$  RF pulse, which requires  $\gamma B_1 \tau = \pi/2$ , where  $\tau$  is the duration of the RF pulse. Another useful RF pulse rotates spins by  $\pi$  radians. This can be used to invert spins. It also can be used to refocus transverse spins that have dephased due to  $B_0$  field inhomogeneity. This is called a **spin echo** and is widely used in imaging.

NMR has been used for decades in chemistry. A complex molecule is placed in a strong, highly uniform magnetic field. Electronic shielding produces microscopic field variations within the molecule so that geometrically isolated nuclei rotate about distinct fields. Each distinct magnetic environment produces a peak in the spectra of the received signal. The relative size of the spectral peaks gives the ratio of nuclei in each magnetic environment. Hence the NMR spectrum is extremely useful for elucidating molecular structure.

The NMR signal from a human is due predominantly to water protons. Since these protons exist in identical magnetic environments, they all resonate at the same frequency. Hence the NMR signal is simply proportional to the volume of the water. Their key innovation for MRI is to impose spatial variations on the magnetic field to distinguish spins by their location. Applying a magnetic field gradient causes each region of the volume to oscillate at a distinct frequency. The most effective nonuniform field is a linear gradient where the field and the resulting frequencies vary linearly with distance along the object being studied. Fourier analysis of the signal obtains a map of the spatial distribution of spins. This argument is formalized below, where we derive the powerful  $k$ -space analysis of MRI [5,6].

### 12.1.1.1 $k$ -Space Analysis of Data Acquisition

In MRI, we receive a volume integral from an array of oscillators. By ensuring that the phase, “signature” of each oscillator is unique, one can assign a unique location to each spin and thereby reconstruct an image. During signal reception, the applied magnetic field points in the  $z$  direction. Spins precess in the  $xy$  plane at the Larmor frequency. Hence a spin at position  $\mathbf{r} = (x, y, z)$  has a unique phase  $\theta$  that describes its angle relative to the  $y$  axis in the  $xy$  plane:

$$s(t) \propto \frac{d}{dt} \int_V M(\mathbf{r}) e^{-i\theta(\mathbf{r},t)/d\tau} \quad (12.1)$$

where  $B_z(\mathbf{r}, t)$  is the  $z$  component of the instantaneous, local magnetic flux density. This formula assumes there are no  $x$  and  $y$  field components.

A coil large enough to receive a time-varying flux uniformly from the entire volume produces an EMF proportional to

$$\theta(\mathbf{r}, t) = -\gamma \int_0^t B_z(\mathbf{r}, \tau) d\tau \quad (12.2)$$

where  $M(\mathbf{r})$  represents the equilibrium moment density at each point  $\mathbf{r}$ .

The key idea for imaging is to superimpose a linear field gradient on the static field  $B_0$ . This field points in the direction  $z$ , and its magnitude varies linearly with a coordinate direction. For example, an  $x$  gradient points in the  $z$  direction and varies along the coordinate  $x$ . This is described by the vector field  $xG_x\hat{\mathbf{z}}$ , where  $\hat{\mathbf{z}}$  is the unit vector in the  $z$  direction. In general, the gradient is  $(xG_x + yG_y + zG_z)\hat{\mathbf{z}}$ , which can be written compactly as the dot product  $\mathbf{G} \cdot \mathbf{r}\hat{\mathbf{z}}$ . These gradient field components can vary with time, so the total  $z$  field is

$$B_z(\mathbf{r}, t) = B_0 + \mathbf{G}(t) \cdot \mathbf{r} \quad (12.3)$$

In the presence of this general time-varying gradient, the received signal is

$$s(t) \propto \frac{d}{dt} \int_V e^{i\gamma B_0 t} M(\mathbf{r}) e^{-i\gamma \int_0^t \mathbf{G}(\tau) \cdot \mathbf{r} d\tau} d\mathbf{r} \quad (12.4)$$

The center frequency  $\gamma B_0$  is always much larger than the bandwidth of the signal. Hence the derivative operation is approximately equivalent to multiplication by  $-i\omega_0$ . The signal is demodulated by the waveform  $e^{i\gamma B_0 t}$  to obtain the “baseband” signal:

$$s(t) \propto -i\omega_0 \int_V M(\mathbf{r}) e^{-i\gamma \int_0^t \mathbf{G}(\tau) \cdot \mathbf{r} d\tau} d\mathbf{r} \quad (12.5)$$

It will be helpful to define the term  $\mathbf{k}(t)$ :

$$\mathbf{k}(t) = \gamma \int_0^t \mathbf{G}(\tau) d\tau \tag{12.6}$$

Then we can rewrite the received baseband signal as

$$S(t) \propto \int_V M(\mathbf{r}) e^{-i\mathbf{k}(t) \cdot \mathbf{r}} d\mathbf{r} \tag{12.7}$$

which we can now identify as the spatial Fourier transform of  $M(\mathbf{r})$  evaluated at  $\mathbf{k}(t)$ . That is,  $S(t)$  scans the spatial frequencies of the function  $M(\mathbf{r})$ . This can be written explicitly as

$$S(t) \propto \mathcal{M}(\mathbf{k}(t)) \tag{12.8}$$

where  $\mathcal{M}(\mathbf{k})$  is the three-dimensional Fourier transform of the object distribution  $M(\mathbf{r})$ . Thus we can view MRI with linear gradients as a “scan” of  $k$ -space or the spatial Fourier transform of the image. After the desired portion of  $k$ -space is scanned, the image  $M(\mathbf{r})$  is reconstructed using an inverse Fourier transform.

**12.1.1.1.1 2D Imaging**

Many different gradient waveforms can be used to scan  $k$ -space and to obtain a desired image. The most common approach, called *two-dimensional Fourier transform imaging (2D FT)*, is to scan through  $k$ -space along several horizontal lines covering a rectilinear grid in 2D  $k$ -space. See Figure 12.1 for a schematic of the  $k$ -space traversal. The horizontal grid lines are acquired using 128 to 256 excitations separated by a time  $TR$ , which is determined by the desired contrast, RF flip angle, and the  $T_1$  of the desired components of the image. The horizontal-line scans through  $k$ -space are offset in  $k_y$  by a variable area  $y$ -gradient pulse, which happens before data acquisition starts. These variable offsets in  $k_y$  are called *phase encodes* because they affect the phase of the signal rather than the frequency. Then for each  $k_y$  phase encode, signal is acquired while scanning horizontally with a constant  $x$  gradient.

**FIGURE 12.1** The drawing on the left illustrates the scanning pattern of the 2D Fourier transform imaging sequence. On the right is a plot of the gradient and RF waveforms that produce this pattern. Only four of the  $N_y$  horizontal  $k$ -space lines are shown. The phase-encode period initiates each acquisition at a different  $k_y$  and at  $-k_x(\text{max})$ . Data are collected during the horizontal traversals. After all  $N_y$   $k$ -space lines have been acquired, a 2D FFT reconstructs the image. Usually 128 or 256  $k_y$  lines are collected, each with 256 samples along  $k_x$ . The RF pulse and the  $z$  gradient waveform together restrict the image to a particular slice through the subject.

### 12.1.1.1.2 Resolution and Field of View

The fundamental image characteristics of resolution and field of view (FOV) are completely determined by the characteristics of the  $k$ -space scan. The extent of the coverage of  $k$ -space determines the resolution of the reconstructed image. The resolution is inversely proportional to the highest spatial frequency acquired:

$$\frac{1}{\Delta x} = \frac{k_x(\text{max})}{\pi} = \frac{\gamma G_x T}{2\pi} \quad (12.9)$$

$$\frac{1}{\Delta y} = \frac{k_y(\text{max})}{\pi} = \frac{\gamma G_y T_{\text{phase}}}{\pi} \quad (12.10)$$

where  $G_x$  is the readout gradient amplitude and  $T$  is the readout duration. The time  $T_{\text{phase}}$  is the duration of the phase-encode gradient  $G_y$ . For proton imaging on a 1.5-T imaging system, a typical gradient strength is  $G_x = 1$  G/cm. The signal is usually read for about 8 msec. For water protons,  $\gamma = 26,751$  rad/sec/G, so the maximum excursion in  $k_x$  is about 21 rad/mm. Hence we cannot resolve an object smaller than 0.3 mm in width. From this one might be tempted to improve the resolution dramatically using very strong gradients or very long readouts. But there are severe practical obstacles, since higher resolution increases the scan time and also degrades the image SNR.

In the phase-encode direction, the  $k$ -space data are sampled discretely. This discrete sampling in  $k$ -space introduces replication in the image domain [7]. If the sampling in  $k$ -space is finer than  $1/\text{FOV}$ , then the image of the object will not fold back on itself. When the  $k$ -space sampling is coarser than  $1/\text{FOV}$ , the image of the object does fold back over itself. This is termed *aliasing*. Aliasing is prevented in the readout direction by the sampling filter.

### 12.1.1.1.3 Perspective

For most imaging systems, diffraction limits the resolution. That is, the resolution is limited to the wavelength divided by the angle subtended by the receiver aperture, which means that the ultimate resolution is approximately the wavelength itself. This is true for imaging systems based on optics, ultrasound, and x-rays (although there are other important factors, such as quantum noise, in x-ray).

MRI is the only imaging system for which the resolution is independent of the wavelength. In MRI, the wavelength is often many meters, yet submillimeter resolution is routinely achieved. The basic reason is that no attempt is made to focus the radiation pattern to the individual pixel or voxel (volume element), as is done in all other imaging modalities. Instead, the gradients create spatially varying magnetic fields so that individual pixels emit unique waveform signatures. These signals are decoded and assigned to unique positions. An analogous problem is isolating the signals from two transmitting antenna towers separated by much less than a wavelength. Directive antenna arrays would fail because of diffraction spreading. However, we can distinguish the two signals if we use the a priori knowledge that the two antennas transmit at different frequencies. We can receive both signals with a wide-angle antenna and then distinguish the signals through frequency-selective filtering.

### 12.1.1.1.4 SNR Considerations

The signal strength is determined by the EMF induced from each voxel due to the processing moments. The magnetic moment density is proportional to the polarizing field  $B_0$ . Recall that the EMF is proportional to the rate of change of the coil flux. The derivative operation multiplies the signal by the Larmor frequency, which is proportional to  $B_0$ , so the received signal is proportional to  $B_0^2$  times the volume of the voxel  $V_v$ .

In a well-designed MRI system, the dominant noise source is due to thermally generated currents within the conductive tissues of the body. These currents create a time-varying flux which induces noise voltages in the receiver coil. Other noise sources include the thermal noise from the antenna and from the first amplifier. These subsystems are designed so that the noise is negligible compared with the noise from the patient. The noise received is determined by the total volume seen by the antenna pattern  $V_n$  and the

effective resistivity and temperature of the conductive tissue. One can show [8] that the standard deviation of the noise from conductive tissue varies linearly with  $B_0$ . The noise is filtered by an integration over the total acquisition time  $T_{acq}$ , which effectively attenuates the noise standard deviation by  $\sqrt{T_{acq}}$ . Therefore, the SNR varies as

$$SNR \propto \frac{B_0^2 V_v}{B_0 V_n / \sqrt{T_{acq}}} = B_0 \sqrt{T_{acq}} (V_v / V_n) \tag{12.11}$$

The noise volume  $V_n$  is the effective volume based on the distribution of thermally generated currents. For example, when imaging a spherical object of radius  $r$ , the noise standard deviation varies as  $r^{5/2}$  [9]. The effective resistance depends strongly on the radius because currents near the outer radius contribute more to the noise flux seen by the receiver coil.

To significantly improve the SNR, most systems use *surface coils*, which are simply small coils that are just big enough to see the desired region of the body. Such a coil effectively maximizes the voxel-volume to noise-volume ratio. The noise is significantly reduced because these coils are sensitive to currents from a smaller part of the body. However, the field of view is somewhat limited, so “phased arrays” of small coils are now being offered by the major manufacturers [10]. In the phased array, each coil sees a small noise volume, while the combined responses provide the wide coverage at a greatly improved SNR.

**12.1.1.1.5 Fast Imaging**

The 2D FT scan of  $k$ -space has the disadvantage that the scan time is proportional to the number of phase encodes. It is often advantageous to trade off SNR for a shorter scan time. This is especially true when motion artifacts dominate thermal noise. To allow for a flexible tradeoff of SNR for imaging time, more than a single line in  $k$ -space must be covered in a single excitation. The most popular approach, called echo-planar imaging (EPI), traverses  $k$ -space back and forth on a single excitation pulse. The  $k$ -space trajectory is drawn in Figure 12.2.

It is important that the tradeoff be flexible so that you can maximize the imaging time given the motion constraints. For example, patients can hold their breath for about 12 sec. So a scan of 12 sec duration gives the best SNR given the breath-hold constraint. The EPI trajectory can be interleaved to take full advantage of the breath-hold interval. If each acquisition takes about a second, 12 interleaves can be collected. Each interleaf acquires every twelfth line in  $k$ -space.

**FIGURE 12.2** Alternative methods for the rapid traversal of  $k$ -space. On the left is the echo planar trajectory. Data are collected during the horizontal traversals. When all  $N_y$  horizontal lines in  $k$ -space have been acquired, the data are sent to a 2D FFT to reconstruct the image. On the right is an interleaved spiral trajectory. The data are interpolated to a 2D rectilinear grid and then Fourier transformed to reconstruct the image. These scanning techniques allow for imaging within a breathhold.

Another trajectory that allows for a flexible tradeoff between scan time and SNR is the spiral trajectory. Here the trajectory starts at the origin in  $k$ -space and spirals outward. Interleaving is accomplished by rotating the spirals. Figure 12.2 shows two interleaves in a spiral format. Interleaving is very helpful for reducing the hardware requirements (peak amplitude, peak slew rate, average dissipation, etc.) for the gradients amplifiers. For reconstruction, the data are interpolated to a 2D rectilinear grid and then Fourier-transformed. Our group has found spiral imaging to be very useful for imaging coronary arteries within a breath-hold scan [11]. The spiral trajectory is relatively immune to artifacts due to the motion of blood.

### 12.1.2 Contrast Mechanisms

The tremendous clinical utility of MRI is due to the great variety of mechanisms that can be exploited to create image contrast. If magnetic resonance images were restricted to water density, MRI would be considerably less useful, since most tissues would appear identical. Fortunately, many different MRI contrast mechanisms can be employed to distinguish different tissues and disease processes.

The primary contrast mechanisms exploit *relaxation* of the magnetization. The two types of relaxations are termed **spin–lattice relaxation**, characterized by a relaxation time  $T_1$ , and **spin–spin relaxation**, characterized by a relaxation time  $T_2$ .

Spin–lattice relaxation describes the rate of recovery of the  $z$  component of magnetization toward equilibrium after it has been disturbed by RF pulses. The recovery is given by

$$M_z(t) = M_0(1 - e^{-t/T_1}) + M_z(0)e^{-t/T_1} \quad (12.12)$$

where  $M_0$  is the equilibrium magnetization. Differences in the  $T_1$  time constant can be used to produce image contrast by exciting all magnetization and then imaging before full recovery has been achieved. This is illustrated on the left in Figure 12.3. An initial  $\pi/2$  RF pulse destroys all the longitudinal magnetization. The plots show the recovery of two different  $T_1$  components. The short  $T_1$  component recovers faster and produces more signal. This gives a  $T_1$ -weighted image.

Spin–spin relaxation describes the rate at which the NMR signal decays after it has been created. The signal is proportional to the transverse magnetization and is given by

$$M_{xy}(t) = M_{xy}(0)e^{-t/T_2} \quad (12.13)$$

**FIGURE 12.3** The two primary MRI contrast mechanisms,  $T_1$  and  $T_2$ .  $T_1$ , illustrated on the left, describes the rate at which the equilibrium  $M_{zk}$  magnetization is restored after it has been disturbed.  $T_1$  contrast is produced by imaging before full recovery has been obtained.  $T_2$ , illustrated on the right, describes the rate at which the MRI signal decays after it has been created.  $T_2$  contrast is produced by delaying data acquisition, so shorter  $T_2$  components produce less signal.

**FIGURE 12.4** Example images of a normal volunteer demonstrating  $T_1$  contrast on the left and  $T_2$  contrast on the right.

Image contrast is produced by delaying the data acquisition. The decay of two different  $T_2$  species is plotted on the right in Figure 12.3. The signal from the shorter  $T_2$  component decays more rapidly, while that of the longer  $T_2$  component persists. At the time of data collection, the longer  $T_2$  component produces more signal. This produces a  $T_2$ -weighted image.

Figure 12.4 shows examples of these two basic types of contrast. These images are of identical axial sections through the brain of a normal volunteer. The image of the left was acquired with an imaging method that produces  $T_1$  contrast. The very bright ring of subcutaneous fat is due to its relatively short  $T_1$ . White matter has a shorter  $T_1$  than gray matter, so it shows up brighter in this image. The image on the right was acquired with an imaging method that produces  $T_2$  contrast. Here the cerebrospinal fluid in the ventricles is bright due to its long  $T_2$ . White matter has a shorter  $T_2$  than gray matter, so it is darker in this image.

There are many other contrast mechanisms that are important in MRI. Different chemical species have slightly different resonant frequencies, and this can be used to image one particular component. It is possible to design RF and gradient waveforms so that the image shows only moving spins. This is of great utility in MR angiography, allowing the noninvasive depiction of the vascular system. Another contrast mechanism is called  $T_2^*$ . This relaxation parameter is useful for functional imaging. It occurs when there is a significant spread of Larmor frequencies within a voxel. The superposition signal is attenuated faster than  $T_2$  due to destructive interference between the different frequencies.

In addition to the intrinsic tissue contrast, artificial MRI contrast agents also can be introduced. These are usually administered intravenously or orally. Many different contrast mechanisms can be exploited, but the most popular agents decrease both  $T_1$  and  $T_2$ . One agent approved for clinical use is gadolinium DPTA. Decreasing  $T_1$  causes faster signal recovery and a higher signal on a  $T_1$ -weighted image. The contrast-enhanced regions then show up bright relative to the rest of the image.

## Defining Terms

**Gyromagnetic ratio  $\gamma$ :** An intrinsic property of a nucleus. It determines the Larmor frequency through the relation  $\omega_0 = -\gamma B_0$ .

**$k$ -space:** The reciprocal of object space,  $k$ -space describes MRI data acquisition in the spatial Fourier transform coordinate system.

- Larmor frequency  $\omega_0$ :** The frequency of precession of the spins. It depends on the product of the applied flux density  $B_0$  and on the gyromagnetic ratio  $\gamma$ . The Larmor frequency is  $\omega_0 = -\gamma B_0$ .
- Magnetization  $M$ :** The macroscopic ensemble of nuclear moments. The moments are induced by an applied magnetic field. At body temperatures, the amount of magnetization is linearly proportional ( $M_0 = 4 \times 10^{-9} H_0$ ) to the applied magnetic field.
- Precession:** The term used to describe the motion of the magnetization about an applied magnetic field. The vector locus traverses a cone. The precession frequency is the frequency of the magnetization components perpendicular to the applied field. The precession frequency is also called the *Larmor frequency*  $\omega_0$ .
- Spin echo:** The transverse magnetization response to a  $\pi$  RF pulse. The effects of field inhomogeneity are refocused at the middle of the spin echo.
- Spin-lattice relaxation  $T_1$ :** The exponential rate constant describing the decay of the  $z$  component of magnetization toward the equilibrium magnetization. Typical values in the body are between 300 and 3000 msec.
- Spin-spin relaxation  $T_2$ :** The exponential rate constant describing the decay of the transverse components of magnetization ( $M_x$  and  $M_y$ ).
- Spins  $M$ :** Another name for magnetization.
- 2D FT:** A rectilinear trajectory through  $k$ -space. This popular acquisition scheme requires several (usually 128 to 256) excitations separated by a time  $TR$ , which is determined by the desired contrast, RF flip angle, and the  $T_1$  of the desired components of the image.

## 12.2 Hardware/Instrumentation

---

### *John Schenck*

This section describes the basic components and the operating principles of MRI scanners. Although scanners capable of making diagnostic images of the human internal anatomy through the use of **magnetic resonance imaging** (MRI) are now ubiquitous devices in the radiology departments of hospitals in the United States and around the world, as recently as 1980 such scanners were available only in a handful of research institutions. Whole-body superconducting magnets became available in the early 1980s and greatly increased the clinical acceptance of this new imaging modality. Market research data indicate that between 1980 and 1996 more than 100 million clinical MRI scans were performed worldwide. By 1996 more than 20 million MRI scans were being performed each year.

MRI scanners use the technique of **nuclear magnetic resonance** (NMR) to induce and detect a very weak radio frequency signal that is a manifestation of **nuclear magnetism**. The term *nuclear magnetism* refers to weak magnetic properties that are exhibited by some materials as a consequence of the nuclear

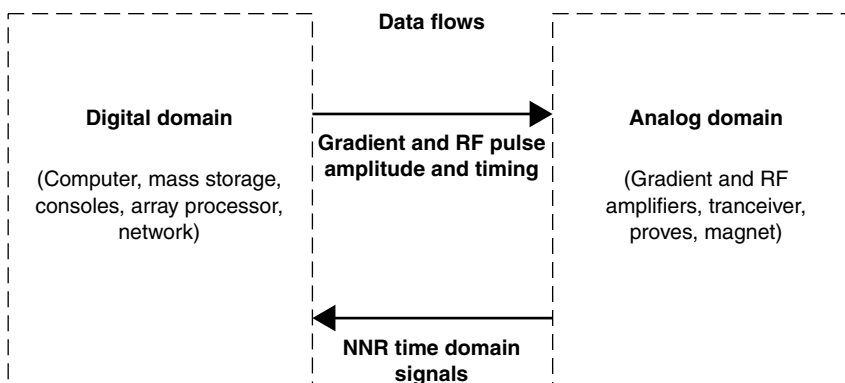

**spin** that is associated with their atomic nuclei. In particular, the proton, which is the nucleus of the hydrogen atom, possesses a nonzero nuclear spin and is an excellent source of NMR signals. The human body contains enormous numbers of hydrogen atoms — especially in water ( $H_2O$ ) and lipid molecules. Although biologically significant NMR signals can be obtained from other chemical elements in the body, such as phosphorous and sodium, the great majority of clinical MRI studies utilize signals originating from protons that are present in the lipid and water molecules within the patient's body.

The patient to be imaged must be placed in an environment in which several different magnetic fields can be simultaneously or sequentially applied to elicit the desired NMR signal. Every MRI scanner utilizes a strong static field magnet in conjunction with a sophisticated set of **gradient coils** and radiofrequency coils. The gradients and the radiofrequency components are switched on and off in a precisely timed pattern, or **pulse sequence**. Different pulse sequences are used to extract different types of data from the patient. MR images are characterized by excellent contrast between the various forms of soft tissues within the body. For patients who have no ferromagnetic foreign bodies within them, MRI scanning appears to be perfectly safe and can be repeated as often as necessary without danger [Shellock and Kanal, 1998]. This provides one of the major advantages of MRI over conventional x-ray and computed tomographic (CT) scanners. The NMR signal is not blocked at all by regions of air or bone within the body, which provides a significant advantage over ultrasound imaging. Also, unlike the case of nuclear medicine scanning, it is not necessary to add radioactive tracer materials to the patient.

### 12.2.1 Fundamentals of MRI Instrumentation

Three types of magnetic fields — main fields or static fields ( $B_2$ ), gradient fields, an radiofrequency (RF) fields ( $B_1$ ) — are required in MRI scanners. In practice, it is also usually necessary to use coils or magnets that produce shimming fields to enhance the spatial uniformity of the static field  $B_0$ . Most MRI hardware engineering is concerned with producing and controlling these various forms of magnetic fields. The ability to construct NMR instruments capable of examining test tube-sized samples has been available since shortly after World War II. The special challenge associated with the design and construction of medical scanners was to develop a practical means of scaling these devices up to sizes capable of safely and comfortably accommodating an entire human patient. Instruments capable of human scanning first became available in the late 1970s. The successful implementation of MRI requires a two-way flow of information between analog and digital formats (Figure 12.5). The main magnet, the gradient and RF coils, and the gradient and RF power supplies operate in the analog domain. The digital domain is centered on a general-purpose computer (Figure 12.6) that is used to provide control information (signal timing and amplitude) to the gradient and RF amplifiers, to process time-domain MRI signal data returning from

**FIGURE 12.5** Digital and analog domains for MRI imaging. MRI involves the flow of data and system commands between these two domains (Courtesy of WM Leue. Reprinted with permission from Schenck and Leue, 1991).

the receiver, and to drive image display and storage systems. The computer also provides miscellaneous control functions, such as permitting the operator to control the position of the patient table.

### 12.2.2 Static Field Magnets

The main field magnet [Thomas, 1993] is required to produce an intense and highly uniform, **static magnetic field** over the entire region to be imaged. To be useful for imaging purposes, this field must be extremely uniform in space and constant in time. In practice, the spatial variation of the main field of a whole-body scanner must be less than about 1 to 10 parts per million (ppm) over a region approximately 40 cm in diameter. To achieve these high levels of homogeneity requires careful attention to magnet design and to manufacturing tolerances. The temporal drift of the field strength is normally required to be less than 0.1 ppm/h.

Two units of magnetic field strength are now in common use. The gauss (G) has a long historical usage and is firmly embedded in the older scientific literature. The tesla (T) is a more recently adopted unit, but is a part of the SI system of units and, for this reason, is generally preferred. The tesla is a much larger unit than the gauss — 1 T corresponds to 10,000 G. The magnitude of the earth’s magnetic field is about 0.05 mT (5000 G). The static magnetic fields of modern MRI scanners are most commonly in the range of 0.5 to 1.5 T; useful scanners, however, have been built using the entire range from 0.02 to 8 T. The signal-to-noise ratio (SNR) is the ratio of the NMR signal voltage to the ever-present noise voltages that arise within the patient and within the electronic components of the receiving system. The SNR is one of the key parameters that determine the performance capabilities of a scanner. The maximum available

SNR increases linearly with field strength. The improvement in SNR as the field strength is increased is the major reason that so much effort has gone into producing high-field magnets for MRI systems.

Magnetic fields can be produced by using either electric currents or permanently magnetized materials as sources. In either case, the field strength falls off rapidly away from the source, and it is not possible to create a highly uniform magnetic field on the outside of a set of sources. Consequently, to produce the highly uniform field required for MRI, it is necessary to more or less surround the patient with a magnet. The main field magnet must be large enough, therefore, to effectively surround the patient; in addition, it must meet other stringent performance requirements. For these reasons, the main field magnet is the most important determinant of the cost, performance, and appearance of an MRI scanner. Four different classes of main magnets — (1) permanent magnets, (2) electromagnets, (3) resistive magnets, and (4) superconducting magnets — have been used in MRI scanners.

### 12.2.2.1 Permanent Magnets and Electromagnets

Both these magnet types use magnetized materials to produce the field that is applied to the patient. In a permanent magnet, the patient is placed in the gap between a pair of permanently magnetized pole faces. Electromagnets use a similar configuration, but the pole faces are made of soft magnetic materials, which become magnetized only when subjected to the influence of electric current coils that are wound around them. Electromagnets, but not permanent magnets, require the use of an external power supply. For both types of magnets, the magnetic circuit is completed by use of a soft iron yoke connecting the pole faces to one another (Figure 12.7). The gap between the pole faces must be large enough to contain the patient as well as the gradient and RF coils. The permanent magnet materials available for use in MRI scanners include high-carbon iron, alloys such as Alnico, ceramics such as barium ferrite, and rare earth alloys such as samarium cobalt.

Permanent magnet scanners have some advantages: they produce a relatively small fringing field and do not require power supplies. However, they tend to be very heavy (up to 100 T) can produce only relatively low fields — on the order of 0.3 T or less. They are also subject to temporal field drift caused by temperature changes. If the pole faces are made from an electrically conducting material, eddy currents induced in the pole faces by the pulsed gradient fields can limit performance as well. A recently introduced

**FIGURE 12.7** Permanent magnet. The figure shows a schematic cross-section of a typical permanent magnet configuration. Electromagnets have a similar construction but are energized by current-carrying coils wound around the iron yoke. Soft magnetic shims are used to enhance the homogeneity of the field. (Reprinted with permission from Schenck and Leue, 1991.)

alloy of neodymium, boron, and iron (usually referred to as *neodymium iron*) has been used to make lighter-weight permanent magnet scanners.

### 12.2.2.2 Resistive Magnets

The first whole-body scanners, manufactured in the late 1970s and early 1980s, used four to six large coils of copper or aluminum wire surrounding the patient. These coils are energized by powerful (40–100 kW) direct-current (dc) power supplies. The electrical resistance of the coils leads to substantial joule heating, and the use of cooling water flowing through the coils is necessary to prevent overheating. The heat dissipation increases rapidly with field strength, and it is not feasible to build resistive magnets operating at fields much higher than 0.15–0.3 T. At present, resistive magnets are seldom used except for very low field strength (0.02–0.06 T) applications.

### 12.2.2.3 Superconducting Magnets

Since the early 1980s, the use of cryogenically cooled superconducting magnets [Wilson, 1983] has been the most satisfactory solution to the problem of producing the static magnet field for MRI scanners. The property of exhibiting absolutely no electrical resistance near absolute zero has been known as an exotic property of some materials since 1911. Unfortunately, the most common of these materials, such as lead, tin, and mercury, exhibit a phase change back to the normal state at relatively low magnetic field strengths and cannot be used to produce powerful magnetic fields. In the 1950s, a new class of materials (type II superconductors) was discovered. These materials retain the ability to carry loss-free electric currents in very high fields. One such material, an alloy of niobium and titanium, has been used in most of the thousands of superconducting whole-body magnets that have been constructed for use in MRI scanners (Figure 12.8). The widely publicized discovery in 1986 of another class of materials which remain superconducting at much higher temperatures than any previously known material has not yet lead to any material capable of carrying sufficient current to be useful in MRI scanners.

Figure 12.9 illustrates the construction of a typical superconducting whole-body magnet. In this case, six coils of superconducting wire are connected in a series and carry an intense current — on the order of 200 A — to produce the 1.5-T magnetic field at the magnet's center. The diameter of the coils is about 1.3 m, and the total length of wire is about 65 km (40 miles). The entire length of this wire must be

**FIGURE 12.8** Superconducting magnet. This figure shows a 1.5-T whole-body superconducting magnet. The nominal warm bore diameter is 1 m. The patient to be imaged, as well as the RF and gradient coils, are located within this bore. (Courtesy of General Electric Medical Systems. Reprinted with permission from Schenck and Leue, 1991.)

**FIGURE 12.9** Schematic drawing of a superconducting magnet. The main magnet coils and the superconducting shim coils are maintained at liquid helium temperature. A computer-controlled table is used to advance the patient into the region of imaging. (Reprinted with permission from Schenck and Leue, 1991.)

without any flaws — such as imperfect welds — that would interrupt the superconducting properties. If the magnet wire has no such flaws, the magnet can be operated in the persistent mode — that is, once the current is established, the terminals may be connected together, and a constant persistent current flow indefinitely so long as the temperature of the coils is maintained below the superconducting transition temperature. This temperature is about 10 K for niobium–titanium wire. The coils are kept at this low temperature by encasing them in a double-walled cryostat (analogous to a Thermos bottle) that permits them to be immersed in liquid helium at a temperature of 4.2 K. The gradual boiling of liquid helium caused by inevitable heat leaks into the cryostat requires that the helium be replaced on a regular schedule. Many magnets now make use of cryogenic refrigerators that reduce or eliminate the need for refilling the liquid helium reservoir. The temporal stability of superconducting magnets operating in the persistent mode is truly remarkable — magnets have operated for years completely disconnected from power supplies and maintained their magnetic field constant to within a few parts per million. Because of their ability to achieve very strong and stable magnetic field strengths without undue power consumption, superconducting magnets have become the most widely used source of the main magnetic fields for MRI scanners.

#### 12.2.2.4 Magnetic Field Homogeneity

The necessary degree of spatial uniformity of the field can be achieved only by carefully placing the coils at specific spatial locations. It is well known that a single loop of wire will produce, on its axis, a field that is directed along the coil axis and that can be expressed as a sum of spherical harmonic fields. The first term in this sum is constant in space and represents the desired field that is completely independent of position. The higher-order terms represent contaminating field inhomogeneities that spoil the field uniformity. More than a century ago, a two-coil magnet system — known as the *Helmholtz pair* — was developed which produced a much more homogeneous field at its center than is produced by a single current loop. This design is based on the mathematical finding that when two coaxial coils of the same radius are separated by a distance equal to their radius, the first nonzero contaminating term in the

harmonic expansion is of the fourth order. This results in an increased region of the field homogeneity, which, although it is useful in many applications, is far too small to be useful in MRI scanners. However, the principle of eliminating low-order harmonic fields can be extended by using additional coils. This is the method now used to increase the volume of field homogeneity to values that are useful for MRI. For example, in the commonly used six-coil system, it is possible to eliminate all the error fields through the twelfth order.

In practice, manufacturing tolerances and field perturbations caused by extraneous magnetic field sources — such as steel girders in the building surrounding the magnet — produce additional inhomogeneity in the imaging region. These field imperfections are reduced by the use of shimming fields. One approach — *active shimming* — uses additional coils (either resistive coils, superconducting coils, or some of each) which are designed to produce a magnetic field corresponding to a particular term in the spherical harmonic expansion. When the magnet is installed, the magnetic field is carefully mapped, and the currents in the shim coils are adjusted to cancel out the terms in the harmonic expansion to some prescribed high order. The alternative approach — *passive shimming* — utilizes small permanent magnets that are placed at the proper locations along the inner walls of the magnet bore to cancel out contaminating fields. If a large object containing magnetic materials — such as a power supply — is moved in the vicinity of superconducting magnets, it may be necessary to reset the shimming currents or magnet locations to account for the changed pattern of field inhomogeneity.

#### 12.2.2.5 Fringing Fields

A large, powerful magnet produces a strong magnetic field in the region surrounding it as well as in its interior. This fringing field can produce undesirable effects such as erasing magnetic tapes (and credit cards). It is also a potential hazard to people with implanted medical devices such as cardiac pacemakers. For safety purposes, it is general practice to limit access to the region where the fringing field becomes intense. A conventional boundary for this region is the “5-gaussline,” which is about 10 to 12 m from the center of an unshielded 1.5-T magnet. Magnetic shielding — in the form of iron plates (passive shielding) or external coils carrying current in the direction opposite to the main coil current (active shielding) — is frequently used to restrict the region in which the fringing field is significant.

### 12.2.3 Gradient Coils

Three gradient fields, one each for the  $x$ ,  $y$ , and  $z$  directions of a Cartesian coordinate system, are used to code position information into the MRI signal and to permit the imaging of thin anatomic slices [Thomas, 1993]. Along with their larger size, it is the use of these gradient coils that distinguishes MRI scanners from the conventional NMR systems such as those used in analytical chemistry. The direction of the static field, along the axis of the scanner, is conventionally taken as the  $z$  direction, and it is only the Cartesian component of the gradient field in this direction that produces a significant contribution to the resonant behavior of the nuclei. Thus, the three relevant gradient fields are  $B_z = G_x X$ ,  $B_z = G_y Y$ , and  $B_z = G_z Z$ . MRI scans are carried out by subjecting the spin system to a sequence of pulsed gradient and RF fields. Therefore, it is necessary to have three separate coils — one for each of the relevant gradient fields — each with its own power supply and under independent computer control. Ordinarily, the most practical method for constructing the gradient coils is to wind them on a cylindrical coil form that surrounds the patient and is located inside the warm bore of the magnet. The  $z$  gradient field can be produced by sets of circular coils wound around the cylinder with the current direction reversed for coils on the opposite sides of the magnet center ( $z = 0$ ). To reduce deviations from a perfectly linear  $B_z$  gradient field, a spiral winding can be used with the direction of the turns reversed at  $z = 0$  and the spacing between windings decreasing away from the coil center (Figure 12.10). A more complex current pattern is required to produce the transverse ( $x$  and  $y$ ) gradients. As indicated in Figure 12.11, transverse gradient fields are produced by windings which utilize a four-quadrant current pattern.

The generation of MR images requires that a rapid sequence of time-dependent gradient fields (on all three axes) be applied to the patient. For example, the commonly used technique of **spin-warp imaging**

**FIGURE 12.10** Z-gradient coil. The photograph shows a spiral coil wound on a cylindrical surface with an overwinding near the end of the coil. (Courtesy of R.J. Dobberstein, General Electric Medical Systems. Reprinted with permission from Schenck and Leue, 1991.)

**FIGURE 12.11** Transverse gradient coil. The photograph shows the outer coil pattern of an actively shielded transverse gradient coil. (Courtesy of R.J. Dobberstien, General Electric Medical Systems. Reprinted with permission from Schenck and Leue, 1991.)

[Edelstein et al., 1980] utilizes a slice-selection gradient pulse to select the spins in a thin (3–10 mm) slice of the patient and then applies readout and phase-encoding gradients in the two orthogonal directions to encode two-dimensional spatial information into the NMR signal. This, in turn, requires that the currents in the three gradient coils be rapidly switched by computer-controlled power supplies. The rate at which gradient currents can be switched is an important determinant of the imaging capabilities of a scanner. In typical scanners, the gradient coils have an electrical resistance of about  $1 \Omega$  and an inductance of

about 1 mH, and the gradient field can be switched from 0 to 10 mT/m (1 G/cm) in about 0.5 msec. The current must be switched from 0 to about 100 A in this interval, and the instantaneous voltage on the coils,  $L di/dt$ , is on the order of 200 V. The power dissipation during the switching interval is about 20 kW. In more demanding applications, such as are met in cardiac MRI, the gradient field may be as high as 4–5 mT/m and switched in 0.2 msec or less. In this case, the voltage required during gradient switching is more than 1 kV. In many pulse sequences, the switching duty cycle is relatively low, and coil heating is not significant. However, fast-scanning protocols use very rapidly switched gradients at a high duty cycle. This places very strong demands on the power supplies, and it is often necessary to use water cooling to prevent overheating the gradient coils.

### 12.2.4 Radiofrequency Coils

**Radiofrequency (RF) coils** are components of every scanner and are used for two essential purposes — transmitting and receiving signals at the resonant frequency of the protons within the patient [Schenck, 1993]. The precession occurs at the **Larmor frequency** of the protons, which is proportional to the static magnetic field. At 1T this frequency is 42.58 MHz. Thus in the range of field strengths currently used in whole-body scanners, 0.02 to 4 T, the operating frequency ranges from 0.85 to 170.3 MHz. For the commonly used 1.5-T scanners, the operating frequency is 63.86 MHz. The frequency of MRI scanners overlaps the spectral region used for radio and television broadcasting. As an example, the frequency of a 1.5-T scanner is within the frequency band 60 to 66 MHz, which is allocated to television channel 3. Therefore, it is not surprising that the electronic components in MRI transmitter and receiver chains closely resemble corresponding components in radio and television circuitry. An important difference between MRI scanners and broadcasting systems is that the transmitting and receiving antennas of broadcast systems operate in the far field of the electromagnetic wave. These antennas are separated by many wavelengths. On the other hand, MRI systems operate in the near field, and the spatial separation of the sources and receivers is much less than a wavelength. In far-field systems, the electromagnetic energy is shared equally between the electric and magnetic components of the wave. However, in the near field of magnetic dipole sources, the field energy is almost entirely in the magnetic component of the electromagnetic wave. This difference accounts for the differing geometries that are most cost effective for broadcast and MRI antenna structures.

Ideally, the RF field is perpendicular to the static field, which is in the  $z$  direction. Therefore, the RF field can be linearly polarized in either the  $x$  or  $y$  direction. However, the most efficient RF field results from quadrature excitation, which requires a coil that is capable of producing simultaneous  $x$  and  $y$  fields with a 90-degree phase shift between them. Three classes of RF coils — body coils, head coils, and surface coils — are commonly used in MRI scanners. These coils are located in the space between the patient and the gradient coils. Conducting shields just inside the gradient coils are used to prevent electromagnetic coupling between the RF coils and the rest of the scanner. Head and body coils are large enough to surround the region being imaged and are designed to produce an RF magnetic field that is uniform across the region to be imaged. Body coils are usually constructed on cylindrical coil forms and have a large enough diameter (50 to 60 cm) to entirely surround the patient's body. Coils are designed only for head imaging (Figure 12.12) have a smaller diameter (typically 28 cm). Surface coils are smaller coils designed to image a restricted region of the patient's anatomy. They come in a wide variety of shapes and sizes. Because they can be closely applied to the region of interest, surface coils can provide SNR advantages over head and body coils for localized regions, but because of their asymmetric design, they do not have uniform sensitivity.

A common practice is to use separate coils for the transmitter and receiver functions. This permits the use of a large coil — such as the body coil — with a uniform excitation pattern as the transmitter and a small surface coil optimized to the anatomic region — such as the spine — being imaged. When this two-coil approach is used, it is important to provide for electronically decoupling of the two coils because they are tuned at the same frequency and will tend to have harmful mutual interactions.

**FIGURE 12.12** Birdcage resonator. This is a head coil designed to operate in a 4-T scanner at 170 MHz. Quadrature excitation and receiver performance are achieved by using two adjacent ports with a 90-degree phase shift between them. (Reprinted with permission from Schenck and Leue, 1991.)

### 12.2.5 Digital Data Processing

A typical scan protocol calls for a sequence of tailored RF and gradient pulses with duration controlled in steps of 0.1 msec. To achieve sufficient dynamic range in control of pulse amplitudes, 12- to 16-bit digital-to-analog converters are used. The RF signal at the Larmor frequency (usually in the range from 1 to 200 MHz) is mixed with a local oscillator to produce a baseband signal which typically has a **bandwidth** of 16–32 kHz. The data-acquisition system must digitize the baseband signal at the Nyquist rate, which requires sampling the detected RF signal at a rate one digital data point every 5–20 msec. Again, it is necessary to provide sufficient dynamic range. Analog-to-digital converters with 16–18 bits are used to produce the desired digitized signal data. During the data acquisition, information is acquired at a rate on the order of 800 kilobytes per second, and each image can contain up to a megabyte of digital data. The array processor (AP) is a specialized computer that is designed for the rapid performance of specific algorithms, such as the **fast Fourier transform (FFT)**, which are used to convert the digitized time-domain data to image data. Two-dimensional images are typically displayed as  $256 \times 128$ ,  $256 \times 256$ , or  $512 \times 512$  **pixel** arrays. The images can be made available for viewing within about 1 sec after data acquisition. Three-dimensional imaging data, however, require more computer processing, and this results in longer delays between acquisition and display.

A brightness number, typically containing 16 bits of gray-scale information, is calculated for each pixel element of the image, and this corresponds to the signal intensity originating in each **voxel** of the object. To make the most effective use of the imaging information, sophisticated display techniques, such as multi-image displays, rapid sequential displays (cine loop), and three-dimensional renderings of anatomic surfaces, are frequently used. These techniques are often computationally intensive and require the use of specialized computer hardware. Interfaces to microprocessor-based workstations are frequently used to provide such additional display and analysis capabilities. MRI images are available as digital data; therefore, there is considerable utilization of local area networks (LANs) to distribute information throughout the hospital, and long-distance digital transmission of the images can be used for purposes of telradiology.

### 12.2.6 Current Trends in MRI

At present, there is a substantial effort directed at enhancing the capabilities and cost-effectiveness of MR imagers. The activities include efforts to reduce the cost of these scanners, improve image quality, reduce scan times, and increase the number of useful clinical applications. Examples of these efforts include the development of high-field scanners, the advent of MRI-guided therapy, and the development of niche scanners that are designed for specific anatomical and clinical applications. Scanners have been developed that are dedicated to low-field imaging of the breast and other designs are dedicated to orthopedic applications such as the knees, wrists, and elbows. Perhaps the most promising incipient application of MRI is to cardiology. Scanners are now being developed to permit studies of cardiac wall motion, cardiac perfusion, and the coronary arteries in conjunction with cardiac stress testing. These scanners emphasize short magnet configurations to permit close monitoring and interaction with the patient, and high strength rapidly switched gradient fields.

Conventional spin-warp images typically require several minutes to acquire. The fast spin echo (FSE) technique can reduce this to the order of 20 sec, and gradient-echo techniques can reduce this time to a few seconds. The echo-planar technique (EPI) [Wehrli, 1990; Cohen and Weisskoff, 1991] requires substantially increased gradient power and receiver bandwidth but can produce images in 40 to 60 msec. Scanners with improved gradient hardware that are capable of handling higher data-acquisition rates are now available.

For most of the 1980s and 1990s, the highest field strength commonly used in MRI scanners was 1.5 T. To achieve better SNRs, higher-field scanners, operating at fields up to 4 T, were studied experimentally. The need for very high-field scanners has been enhanced by the development of functional brain MRI. This technique utilizes magnetization differences between oxygenated and deoxygenated hemoglobin, and this difference is enhanced at higher field strengths. It has now become possible to construct 3- and 4-T and even 8-T [Robitaille et al., 1998], whole-body scanners of essentially the same physical size (or footprint) as conventional 1.5-T systems. Along with the rapidly increasing clinical interest in functional MRI, this is resulting in a considerable increase in the use of high-field systems.

For the first decade or so after their introduction, MRI scanners were used almost entirely to provide diagnostic information. However, there is now considerable interest in systems capable of performing image-guided, invasive surgical procedures. Because MRI is capable of providing excellent soft-tissue contrast and has the potential for providing excellent positional information with submillimeter accuracy, it can be used for guiding biopsies and stereotactic surgery. The full capabilities of MRI-guided procedures can only be achieved if it is possible to provide surgical access to the patient simultaneously with the MRI scanning. This has led to the development of new system designs, including the introduction of a scanner with a radically modified superconducting magnet system that permits the surgeon to operate at the patient's side within the scanner (Figure 12.13) [Schenck et al., 1995; Black et al., 1997]. These systems have led to the introduction of magnetic field-compatible surgical instruments, anesthesia stations, and patient monitoring equipment [Schenck, 1996].

### Defining Terms

**Bandwidth:** The narrow frequency range, approximately 32 kHz, over which the MRI signal is transmitted. The bandwidth is proportional to the strength of the readout gradient field.

**Echo-planar imaging (EPI):** A pulse sequence used to produce very fast MRI scans. EPI times can be as short as 50 msec.

**Fast Fourier transform (FFT):** A mathematical technique used to convert data sampled from the MRI signal into image data. This version of the Fourier transform can be performed with particular efficiency on modern array processors.

**Gradient coil:** A coil designed to produce a magnetic field for which the field component  $B_z$  varies linearly with position. Three gradient coils, one each for the  $x$ ,  $y$ , and  $z$  directions, are required MRI. These coils are used to permit slice selection and to encode position information into the MRI signal.

**FIGURE 12.13** Open magnet for MEI-guided therapy. This open-geometry superconducting magnet provides a surgeon with direct patient access and the ability to interactively control the MRI scanner. This permits imaging to be performed simultaneously with surgical interventions.

**Larmor frequency:** The rate at which the magnetic dipole moment of a particle precesses in an applied magnetic field. It is proportional to the field strength and is 42.58 MHz for protons in a 1-T magnetic field.

**Magnetic resonance imaging (MRI):** A technique for obtaining images of the internal anatomy based on the use of nuclear magnetic resonance signals. During the 1980s, it became a major modality for medical diagnostic imaging.

**Nuclear magnetic resonance (NMR):** A technique for observing and studying nuclear magnetism. It is based on partially aligning the nuclear spins by use of a strong, static magnetic field, stimulating these spins with a radiofrequency field oscillating at the Larmor frequency, and detecting the signal that is induced at this frequency.

**Nuclear magnetism:** The magnetic properties arising from the small magnetic dipole moments possessed by the atomic nuclei of some materials. This form of magnetism is much weaker than the more familiar form that originates from the magnetic dipole moments of the atomic electrons.

**Pixel:** A single element or a two-dimensional array of image data.

**Pulse sequence:** A series of gradient and radiofrequency pulses used to organize the nuclear spins into a pattern that encodes desired imaging information into the NMR signal.

**Quadrature excitation and detection:** The use of circularly polarized, rather than linearly polarized, radio frequency fields to excite and detect the NMR signal. It provides a means of reducing the required excitation power by 1/2 and increasing the signal-to-noise ratio by 2.

**Radiofrequency (RF) coil:** A coil designed to excite and/or detect NMR signals. These coils can usually be tuned to resonate at the Larmor frequency of the nucleus being studied.

**Spin:** The property of a particle, such as an electron or nucleus, that leads to the presence of an intrinsic angular momentum and magnetic moment.

**Spin-warp imaging:** The pulse sequence used in the most common method of MRI imaging. It uses a sequence of gradient field pulses to encode position information into the NMR signal and applies Fourier transform mathematics to this signal to calculate the image intensity value for each pixel.

**Static magnetic field:** The field of the main magnet that is used to magnetize the spins and to drive their Larmor precession.

**Voxel:** The volume element associated with a pixel. The voxel volume is equal to the pixel area multiplied by the slice thickness.

## Further Information

There are several journals devoted entirely to MR imaging. These include *Magnetic Resonance in Medicine*, *JMRI — Journal of Magnetic Resonance Imaging*, and *NMR in Biomedicine*, all three of which are published by Wiley-Liss, 605 Third Avenue, New York, NY 10158. Another journal dedicated to this field is *Magnetic Resonance Imaging* (Elsevier Publishing, 655 Avenue of the Americas, New York, NY 10010). The clinical aspects of MRI are covered extensively in *Radiology* (Radiological Society of North America, 2021 Spring Road, Suite 600, Oak Brook, IL 60521), *The American Journal of Radiology* (American Roentgen Ray Society, 1891 Preston White Drive, Reston, VA 20191), as well as in several other journals devoted to the practice of radiology. There is a professional society, now known as the International Society for Magnetic Resonance in Medicine (ISMRM), devoted to the medical aspects of magnetic resonance. The main offices of this society are at 2118 Milvia, Suite 201, Berkeley, CA 94704. This society holds an annual meeting that includes displays of equipment and the presentation of approximately 2800 technical papers on new developments in the field. The annual *Book of Abstracts* of this meeting provides an excellent summary of current activities in the field. Similarly, the annual meeting of the Radiological Society of North America (RSNA) provides extensive coverage of MRI that is particularly strong on the clinical applications. The RSNA is located at 2021 Spring Road, Suite 600, Oak Brook, IL 60521.

Several book-length accounts of MRI instrumentation and techniques are available. *Biomedical Magnetic Resonance Technology* [Adam Higler, Bristol, 1989] by Chen and D.I. Hoult, *The Physics of MRI* (Medical Physics Monograph 21, American Institute of Physics, Woodbury, NY, 1993), edited by

M.J. Bronskill and P. Sprawls, and *Electromagnetic Analysis and Design in Magnetic Resonance Imaging* (CRC Press, Boca Raton, FL, 1998) by J.M. Jin each contain thorough accounts of instrumentation and the physical aspects of MRI. There are many books that cover the clinical aspects of MRI. Of particular interest are *Magnetic Resonance Imaging*, 3rd edition [Mosby, St. Louis, 1999], edited by D.D. Stark and W.G. Bradley, Jr., and *Magnetic Resonance Imaging of the Brain and Spine*, 2nd ed. (Lippincott-Raven, Philadelphia, 1996), edited by S.W. Atlas.

## 12.3 Functional MRI

*Kenneth K. Kwong and David A. Chesler*

Functional magnetic resonance imaging (fMRI), a technique that images intrinsic blood signal change with magnetic resonance (MR) imagers, has in the last 3 years become one of the most successful tools used to study blood flow and perfusion in the brain. Since changes in neuronal activity are accompanied by focal changes in cerebral blood flow (CBF), blood volume (CBV), blood oxygenation, and metabolism, these physiologic changes can be used to produce functional maps of mental operations.

There are two basic but completely different techniques used in fMRI to measure CBF. The first one is a classic steady-state perfusion technique first proposed by Detre et al. [1], who suggested the use of saturation or inversion of incoming blood signal to quantify absolute blood flow [1–5]. By focusing on blood flow *change* and not just steady-state blood flow, Kwong et al. [6] were successful in imaging brain visual functions associated with quantitative perfusion change. There are many advantages in studying blood flow change because many common baseline artifacts associated with MRI absolute flow techniques can be subtracted out when we are interested only in changes. And one obtains adequate information in most functional neuroimaging studies with information of flow change alone.

The second technique also looks at change of a blood parameter — blood oxygenation *change* during neuronal activity. The utility of the change of blood oxygenation characteristics was strongly evident in Turner's work [7] with cats with induced hypoxia. Turner et al. found that with hypoxia, the MRI signal from the cats' brains went down as the level of deoxyhemoglobin rose, a result that was an extension of an earlier study by Ogawa et al. [8,9] of the effect of deoxyhemoglobin on MRI signals in animals' veins. Turner's new observation was that when oxygen was restored, the cats' brain signals climbed up and went *above* their baseline levels. This was the suggestion that the vascular system overcompensated by bringing more oxygen, and with more oxygen in the blood, the MRI signal would rise beyond the baseline.

Based on Turner's observation and the perfusion method suggested by Detre et al., movies of human visual cortex activation utilizing both the perfusion and blood oxygenation techniques were successfully acquired in May of 1991 (Figure 12.14) at the Massachusetts General Hospital with a specially equipped superfast 1.5-T system known as an *echo-planar imaging* (EPI) MRI system [10]. fMRI results using intrinsic blood contrast were first presented in public at the Tenth Annual Meeting of the Society of Magnetic Resonance in Medicine in August of 1991 [6,11]. The visual cortex activation work was carried out with flickering goggles, a photic stimulation protocol employed by Belliveau et al. [12] earlier to acquire the MRI functional imaging of the visual cortex with the injection of the contrast agent gadolinium-DTPA. The use of an external contrast agent allows the study of change in blood volume. The intrinsic blood contrast technique, sensitive to blood flow and blood oxygenation, uses no external contrast material. Early model calculation showed that signal due to blood perfusion change would only be around 1% above baseline, and the signal due to blood oxygenation change also was quite small. It was quite a pleasant surprise that fMRI results turned out to be so robust and easily detectable.

The blood oxygenation-sensitive MRI signal change, coined *blood oxygenation level dependent* (BOLD) by Ogawa et al. [8,9,13], is in general much larger than the MRI perfusion signal change during brain activation. Also, while the first intrinsic blood contrast fMRI technique was demonstrated with a superfast EPI MRI system, most centers doing fMRI today are only equipped with conventional MRI systems, which are really not capable of applying Detre's perfusion method. Instead, the explosive growth of MR functional

**FIGURE 12.14** Functional MR image demonstrating activation of the primary visual cortex (V1). Image acquired on May 9, 1991 with a blood oxygenation–sensitive MRI gradient-echo (GE) technique.

neuroimaging [14–33] in the last three years relies mainly on the measurement of blood oxygenation change, utilizing a MR parameter called  $T_2$ . Both high speed echo planar (EPI) and conventional MR have now been successfully employed for functional imaging in MRI systems with magnet field strength ranging from 1.5 to 4.0 T.

### 12.3.1 Advances in Functional Brain Mapping

The popularity of fMRI is based on many factors. It is safe and totally noninvasive. It can be acquired in single subjects for a scanning duration of several minutes, and it can be repeated on the same subjects as many times as necessary. The implementation of the blood oxygenation sensitive MR technique is universally available. Early neuroimaging work focused on time-resolved MR topographic mapping of human primary visual (VI) (Figure 12.15 and Figure 12.16), motor (MI), somatosensory (S1), and auditory (A1) cortices during task activation. Today, with BOLD technique combined with EPI, one can acquire 20 or more contiguous brain slices covering the whole head ( $3 \times 3$  mm in plane and 5 mm slice thickness) every 3 sec for a total duration of several minutes. Conventional scanners can only acquire a couple of slices at a time. The benefits of whole-head imaging are many. Not only can researchers identify and test their hypotheses on known brain activation centers, they can also search for previous unknown or unsuspected sites. High resolution work done with EPI has a resolution of  $1.5 \times 1.5$  mm in plane and a slice thickness of 3 mm. Higher spatial resolution has been reported in conventional 1.5-T MR systems [34].

Of note with Figure 12.16 is that with blood oxygenation–sensitive MR technique, one observes an undershoot [6,15,35] in signal in V1 when the light stimulus is turned off. The physiologic mechanism underlying the undershoot is still not well understood.

The data collected in the last 3 years have demonstrated that fMRI maps of the visual cortex correlate well with known retinotopic organization [24,36]. Higher visual regions such as V5/MT [37] and motor-cortex organization [6,14,27,38] have been explored successfully. Preoperative planning work (Figure 12.17) using motor stimulation [21,39,40] has helped neurosurgeons who attempt to preserve primary areas from tumors to be resected. For higher cognitive functions, several fMRI language studies have already demonstrated known language-associated regions [25,26,41,42] (Figure 12.18). There is more detailed modeling work on the mechanism of functional brain mapping by blood-oxygenation change [43–46]. Postprocessing techniques that would help to alleviate the serious problem of motion/displacement artifacts are available [47].

**FIGURE 12.15** Movie of fMRI mapping of primary visual cortex (V1) activation during visual stimulation. Images are obliquely aligned along the calcarine fissures with the occipital pole at the bottom. Images were acquired at 3-sec intervals using a blood oxygenation–sensitive MRI sequence (80 images total). A baseline image acquired during darkness (*upper left*) was subtracted from subsequent images. Eight of these subtraction images are displayed, chosen when the image intensities reached a steady-state signal level during darkness (OFF) and during 8-Hz photic stimulation (ON). During stimulation, local increases in signal intensity are detected in the posteromedial regions of the occipital lobes along the calcarine fissures.

### 12.3.2 Mechanism

Flow-sensitive images show increased perfusion with stimulation, while blood oxygenation–sensitive images show changes consistent with an increase in venous blood oxygenation. Although the precise biophysical mechanisms responsible for the signal changes have yet to be determined, good hypotheses exist to account for our observations.

Two fundamental MRI relaxation rates,  $T_1$  and  $T_2$ , are used to describe the fMRI signal.  $T_1$  is the rate at which the nuclei approach thermal equilibrium, and perfusion change can be considered as an additional  $T_1$  change.  $T_2$  represents the rate of the decay of MRI signal due to magnetic field inhomogeneities, and the change of  $T_2$  is used to measure blood-oxygenation change.

$T_2$  changes reflect the interplay between changes in cerebral blood flow, volume, and oxygenation. As hemoglobin becomes deoxygenated, it becomes more paramagnetic than the surrounding tissue [48] and thus creates a magnetically inhomogeneous environment. The observed *increased* signal on  $T_2$ -weighted images during activation reflects a decrease in deoxyhemoglobin content, that is, an increase in venous blood oxygenation. Oxygen delivery, cerebral blood flow, and cerebral blood volume all increase with neuronal activation. Because CBF (and hence oxygen-delivery) changes exceed CBV changes by 2 to 4 times [49], while blood–oxygen extraction increases only slightly [50,51], the total paramagnetic blood deoxyhemoglobin content within brain tissue voxels will decrease with brain activation. The resulting decrease in the tissue-blood magnetic susceptibility difference leads to less intravoxel dephasing within brain tissue voxels and hence *increased* signal on  $T_2$ -weighted images [6,14,15,17]. These results independently confirm PET observations that activation-induced changes in blood flow and volume are accompanied by little or no increases in tissue oxygen consumption [50–52].

**FIGURE 12.16** Signal intensity changes for a region of interest ( $\sim 60 \text{ mm}^2$ ) within the visual cortex during darkness and during 8-Hz photic stimulation. Results using oxygenation-sensitive (*top graph*) and flow-sensitive (*bottom graph*) techniques are shown. The flow-sensitive data were collected once every 3.5 sec, and the oxygenation-sensitive data were collected once every 3 sec. Upon termination of photic stimulation, an undershoot in the oxygenation-sensitive signal intensity is observed.

Since the effect of volume susceptibility difference  $\Delta\chi$  is more pronounced at high field strength [53], higher-field imaging magnets [17] will increase the observed  $T_2$  changes.

Signal changes can also be observed on  $T_1$ -weighted MR images. The relationship between  $T_1$  and regional blood flow was characterized by Detre et al. [1]:

$$\frac{dM}{dt} = \frac{M_0 - M}{T_1} + fM_b - \frac{f}{\lambda}M \tag{12.14}$$

where  $M$  is tissue magnetization and  $M_b$  is incoming blood signal.  $M_0$  is proton density,  $f$  is the flow in ml/gm/unit time, and  $\lambda$  is the brain–blood partition coefficient of water ( $\sim 0.95 \text{ ml/g}$ ). From this equation, the brain tissue magnetization  $M$  relaxes with an apparent  $T_1$  time constant  $T_{1 \text{ app}}$  given by

$$\frac{f}{\lambda} = \frac{1}{T_{1 \text{ app}}} - \frac{1}{T_1} \tag{12.15}$$

where the  $T_{1 \text{ app}}$  is the observed (apparent) longitudinal relaxation time with flow effects included.  $T_1$  is the true tissue longitudinal relaxation time in the absence of flow. If we assume that the true tissue  $T_1$

**FIGURE 12.17** Functional MRI mapping of motor cortex for preoperative planning. This three-dimensional rendering of the brain represents fusion of functional and structural anatomy. Brain is viewed from the top. A tumor is shown in the left hemisphere, near the midline. The other areas depict sites of functional activation during movement of the right hand, right foot, and left foot. The right foot cortical representation is displaced by tumor mass effect from its usual location. (Courtesy of Dr. Brad Buchbinder.)

remains constant with stimulation, a change in blood flow  $\Delta f$  will lead to a change in the observed  $T_{1\text{ app}}$ :

$$\Delta \frac{1}{T_{1\text{ app}}} = \Delta \frac{f}{\lambda} \quad (12.16)$$

Thus the MRI signal change can be used to estimate the change in blood flow.

From Equation 12.14, if the magnetization of blood and tissue always undergoes a similar  $T_1$  relaxation, the flow effect would be minimized. This is a condition that can be approximated by using a flow-nonsensitive  $T_1$  technique inverting *all* the blood coming into the imaged slice of interest. This flow-nonsensitive sequence can be subtracted from a flow-sensitive  $T_1$  technique to provide an index of CBF without the need of external stimulation [54,55] (Figure 12.19). Initial results with tumor patients show that such flow-mapping techniques are useful for mapping out blood flow of tumor regions [55].

Other flow techniques under investigation include the continuous inversion of incoming blood at the carotid level [1] or the use of a single inversion pulse at the carotid level (EPIstar) inverting the incoming blood [56,57]. Compared with the flow-nonsensitive and flow-sensitive methods, the blood-tagging techniques at the carotid level are basically similar concepts except that the MRI signal of tagged blood is expected to be smaller by a factor that depends on the time it takes blood to travel from the tagged site to the imaged slice of interest [55]. The continuous-inversion technique also has a significant problem of magnetization transfer [1] that contaminates the flow signal with a magnetization transfer signal that is several times larger. On the other hand, the advantage of the continuous inversion is that it can under optimal conditions provide a flow contrast larger than all the other methods by a factor of  $e$  [55].

**FIGURE 12.18** Left hemisphere surface rendering of functional data (EPI, gradient-echo, ten oblique coronal slices extending to posterior sylvian fissure) and high-resolution anatomic image obtained on a subject (age 33 years) during performance of a same-different (visual matching) task of pairs of words or nonwords (false font strings). Foci of greatest activation for this study are located in dominant perisylvian cortex, that is, inferior frontal gyrus (Broca's area), superior temporal gyrus (Wernicke's area), and inferior parietal lobule (angular gyrus). Also active in this task are sensorimotor cortex and prefrontal cortex. The perisylvian sites of activation are known to be key nodes in a left hemisphere language network. Prefrontal cortex probably plays a more general, modulatory role in attentional aspects of the task. Sensorimotor activation is observed in most language studies despite the absence of overt vocalization. (Courtesy of Dr. Randall Benson.)

**FIGURE 12.19** Functional MRI cerebral blood flow (CBF) index (*right*) of a low-flow brain tumor (dark region right of the midline) generated by the subtraction of a flow-nonsensitive image from a flow-sensitive image. This low-flow region matches well with a cerebral blood volume (CBV) map (*left*) of the tumor region generated by the injection of a bolus of MRI contrast agent Gd-DTPA, a completely different and established method to measure hemodynamics with MRI.

**FIGURE 12.20** The curves represent time courses of MRI response to photic stimulation (off-on-off-on ...) with different levels of velocity-dephasing gradients turned on to remove MRI signals coming from the flowing blood of large vessels. The top curve had no velocity-dephasing gradients turned on. The bottom curve was obtained with such strong velocity-dephasing gradients turned on that all large vessel signals were supposed to have been eliminated. The middle curve represents a moderate amount of velocity-dephasing gradients, a tradeoff between removing large vessel signals and retaining a reasonable amount of MRI signal to noise.

### 12.3.3 Problem and Artifacts in fMRI: The Brain-Vein Problem? The Brain-Inflow Problem?

The artifacts arising from large vessels pose serious problems to the interpretation of oxygenation sensitive fMRI data. It is generally believed that microvascular changes are specific to the underlying region of neuronal activation. However, MRI gradient echo (GE) is sensitive to vessels of all dimensions [46,58], and there is concern that macrovascular changes distal to the site of neuronal activity can be induced [20]. This has been known as the *brain-vein problem*. For laboratories not equipped with EPI, gradient echo (GE) sensitive to variations in  $T_2$  and magnetic susceptibility are the only realistic sequences available for fMRI acquisition, so the problem is particularly acute.

In addition, there is a non-deoxyhemoglobin-related problem, especially acute in conventional MRI. This is the inflow problem of fresh blood that can be time-locked to stimulation [28,29,59]. Such nonparenchymal and macrovascular responses can introduce error in the estimate of activated volumes.

### 12.3.4 Techniques to Reduce the Large Vessel Problems

In dealing with the inflow problems, EPI has special advantages over conventional scanners. The use of long repetition times (2 to 3 sec) in EPI significantly reduces the brain-inflow problem. Small-flip-angle methods in conventional MRI scanners can be used to reduce inflow effect [59]. Based on inflow modeling, one observes that at an angle smaller than the Ernst angle [60], the inflow effect drops much faster than the tissue signal response to activation. Thus one can effectively remove the inflow artifacts with small-flip-angle techniques.

A new exciting possibility is to add small additional velocity-dephasing gradients to suppress slow in-plane vessel flow [60,61]. Basically, moving spins lose signals, while stationary spins are unaffected. The addition of these velocity-dephasing gradients drops the overall MRI signal (Figure 12.20). The hypothesis that large vessel signals are suppressed while tissue signals remain intact is a subject of ongoing research.

Another advantage with EPI is that another oxygenation-sensitive method such as the EPI  $T_2$ -weighted spin-echo (T2SE) is also available. T2SE methods are sensitive to the MRI parameter  $T_2$ , which is affected by microscopic susceptibility and hence blood oxygenation. Theoretically, T2SE methods are far less sensitive to large vessel signals [1,6,46,58]. For conventional scanners, T2SE methods take too long to perform and therefore are not practical options.

The flow model [1] based on  $T_1$ -weighted sequences and independent of deoxyhemoglobin is also not so prone to large vessel artifacts, since the  $T_1$  model is a model of perfusion at the tissue level.

Based on the study of volunteers, the average  $T_2$ -weighted GE signal percentage change at V1 was  $2.5 \pm 0.8\%$ . The average oxygenation-weighted T2SE signal percentage change was  $0.7 \pm 0.3\%$ . The average perfusion-weighted and  $T_1$ -weighted MRI signal percentage change was  $1.5 \pm 0.5\%$ . These results demonstrate that T2SE and  $T_1$  methods, despite their ability to suppress large vessels, are not competitive with  $T_2$  effect at 1.5 T. However, since the microscopic effect detected by T2SE scales up with field strength [62], we expect the T2SE to be a useful sequence at high field strength such as 3 or 4 T. Advancing field strength also should benefit  $T_1$  studies due to better signal-to-noise and to the fact that  $T_1$  gets longer at higher field strength.

While gradient-echo sequence has a certain ambiguity when it comes to tissue versus vessels, its sensitivity at current clinical field strength makes it an extremely attractive technique to identify activation sites. By using careful paradigms that rule out possible links between the primary activation site and secondary sites, one can circumvent many of the worries of "signal from the primary site draining down to secondary sites." A good example is as follows: photic stimulation activates both the primary visual cortex and the extrastriates. To show that the extrastriates are not just a drainage from the primary cortex, one can utilize paradigms that activate the primary visual cortex but not the extrastriate, and vice versa. There are many permutations of this [37]. This allows us to study the higher-order functions unambiguously even if we are using gradient-echo sequences.

The continuous advance of MRI mapping techniques utilizing intrinsic blood-tissue contrast promises the development of a functional human neuroanatomy of unprecedented spatial and temporal resolution.

## 12.4 Chemical-Shift Imaging: An Introduction to Its Theory and Practice

---

*Xiaoping Hu, Wei Chen, Maqbool Patel, and Kamil Ugurbil*

Over the past two decades, there has been a great deal of development in the application of nuclear magnetic resonance (NMR) to biomedical research and clinical medicine. Along with the development of magnetic resonance imaging [1], *in vivo* magnetic resonance spectroscopy (MRS) is becoming a research tool for biochemical studies of humans as well as a potentially more specific diagnostic tool, since it provides specific information on individual chemical species in living systems. Experimental studies in animals and humans have demonstrated that MRS can be used to study the biochemical basis of disease and to follow the treatment of disease.

Since biologic subjects (e.g., humans) are heterogeneous, it is necessary to spatially localize the spectroscopic signals to a well-defined volume or region of interest (VOI or ROI, respectively) in the intact body. Toward this goal, various localization techniques have been developed (see Reference 2 for a recent review). Among these techniques, chemical-shift imaging (CSI) or spectroscopic imaging [3–6] is an attractive technique, since it is capable of producing images reflecting the spatial distribution of various chemical species of interest. Since the initial development of CSI in 1982 [3], further developments have been made to provide better spatial localization and sensitivity, and the technique has been applied to numerous biomedical problems.

In this section we will first present a qualitative description of the basic principles of chemical-shift imaging and subsequently present some practical examples to illustrate the technique. Finally, a summary is provided in the last subsection.

### 12.4.1 General Methodology

In an NMR experiment, the subject is placed in a static magnetic field  $B_0$ . Under the equilibrium condition, nuclear spins with nonzero magnetic moment are aligned along  $B_0$ , giving rise to an induced bulk magnetization. To observe the bulk magnetization, it is tipped to a direction perpendicular to  $B_0$  (transverse plane) with a radiofrequency (RF) pulse that has a frequency corresponding to the resonance frequency of the nuclei. The resonance frequency is determined by the product of the gyromagnetic ratio of the nucleus  $\gamma$  and the strength of the static field, that is,  $\gamma B_0$ , and is called the *Larmor frequency*. The Larmor frequency also depends on the chemical environment of the nuclei, and this dependency gives rise to chemical shifts that allow one to identify different chemical species in an NMR spectrum. Upon excitation, the magnetization in the transverse plane (perpendicular to the main  $B_0$  field direction) oscillates with the Larmor frequencies of all the different chemical species and induces a signal in a receiving RF coil; the signal is also termed the *free induction decay (FID)*. The FID can be Fourier transformed with respect to time to produce a spectrum in frequency domain.

In order to localize an NMR signal from an intact subject, spatially selective excitation and/or spatial encoding are usually utilized. Selective excitation is achieved as follows: in the excitation, an RF pulse with a finite bandwidth is applied in the presence of a linear static magnetic field gradient. With the application of the gradient, the Larmor frequency of spins depends linearly on the spatial location along the direction of the gradient. Consequently, only the spins in a slice whose resonance frequency falls into the bandwidth of the RF pulse are excited.

The RF excitation rotates all or a portion of the magnetization to the transverse plane, which can be detected by a receiving RF coil. Without spatial encoding, the signal detected is the integral of the signals over the entire excited volume. In CSI based on Fourier imaging, spatial discrimination is achieved by phase encoding. Phase encoding is accomplished by applying a gradient pulse after the excitation and before the data acquisition. During the gradient pulse, spins precess at Larmor frequencies that vary linearly along the direction of the gradient and accrue a phase proportional to the position along the phase-encoding gradient as well as the strength and the duration of the gradient pulse. This acquired spatially encoded

phase is typically expressed as  $\vec{k} \cdot \vec{r} = \int \gamma \vec{g}(t) \cdot \vec{r} dt$ , where  $\gamma$  is the gyromagnetic ratio;  $\vec{r}$  is the vector designating spatial location;  $\vec{g}(t)$  defines the magnitude, the direction, and the time dependence of the magnetic field gradient applied during the phase-encoding; and the integration is performed over time when the phase-encoding gradient is on. Thus, in one-dimensional phase encoding, if the phase encoding is along, for example, the  $y$  axis, the phase acquired becomes  $k \times y = \int \gamma g_y(t) \times y dt$ . The acquired signal  $S(t)$  is the integral of the spatially distributed signals modulated by a spatially dependent phase, given by the equation

$$S(t) = \int \rho(\vec{r}, t) e^{i\vec{k} \cdot \vec{r}} d^3 r \quad (12.17)$$

where  $\rho$  is a function that describes the spatial density and the time evolution of the transverse magnetization of all the chemical species in the sample. This signal mathematically corresponds to a sample of the Fourier transform along the direction of the gradient. The excitation and detection process is repeated with various phase-encoding gradients to obtain many phase-encoded signals that can be inversely Fourier-transformed to resolve an equal number of pixels along this direction. Taking the example of one-dimensional phase-encoding along the  $y$  axis to obtain a one-dimensional image along this direction of  $n$  pixels, the phase encoding gradient is incremented  $n$  times so that  $n$  FIDs are acquired, each of which is described as

$$S(t, n) = \int \rho^*(y, t) e^{i(nk_0 y)} dy \quad (12.18)$$

where  $\rho^*$  is already integrated over the  $x$  and  $z$  directions, and  $k_0$  is the phase-encoding increment; the latter is decided on using the criteria that the full field of view undergo a 360-degree phase difference when  $n = 1$ , as dictated by the sampling theorem. The time required for each repetition ( $TR$ ), which is dictated by the longitudinal relaxation time, is usually on the order of seconds.

In CSI, phase encoding is applied in one, two, or three dimensions to provide spatial localization. Meanwhile, selective excitation also can be utilized in one or more dimensions to restrict the volume to be resolved with the phase encodings. For example, with selective excitation in two dimensions, CSI in one spatial dimension can resolve voxels within the selected column. In multidimensional CSI, all the phase-encoding steps along one dimension need to be repeated for all the steps along the others. Thus, for three dimensions with  $M$ ,  $N$ , and  $L$  number of phase encoding steps, one must acquire  $M \times N \times L$  number of FIDS:

$$S(t, m, n, l) = \int \rho(\vec{r}, t) e^{i(mk_{x0}x + nk_{y0}y + lk_{z0}z)} d^3 \vec{r} \quad (12.19)$$

where  $m$ ,  $n$ , and  $l$  must step through  $M$ ,  $N$ , and  $L$  in integer steps, respectively. As a result, the time needed for acquiring a chemical-shift image is proportional to the number of pixels desired and may be very long. In practice, due to the time limitation as well as the signal-to-noise ratio (SNR) limitation, chemical-shift imaging is usually performed with relatively few spatial encoding steps, such as  $16 \times 16$  or  $32 \times 32$  in a two-dimensional experiment.

The data acquired with the CSI sequence need to be properly processed before the metabolite information can be visualized and quantitated. The processing consists of spatial reconstruction and spectral processing. Spatial reconstruction is achieved by performing discrete inverse Fourier transformation, for each of the spatial dimensions, with respect to the phase-encoding steps. The spatial Fourier transform is applied for all the points of the acquired FID. For example, for a data set from a CSI in two spatial dimensions with  $32 \times 32$  phase-encoding steps and 1024 sampled data points for each FID, a  $32 \times 32$  two-dimensional inverse Fourier transform is applied to each of the 1024 data points. Although the nominal spatial resolution achieved by the spatial reconstruction is determined by the number of phase-encoding steps and the field of view (FOV), it is important to note that due to the limited number

of phase-encoding steps used in most CSI experiments, the spatial resolution is severely degraded by the truncation artifacts, which results in signal “bleeding” between pixels. Various methods have been developed to reduce this problem [7–14].

The localized FIDs derived from the spatial reconstruction are to be further processed by spectral analysis. Standard procedures include Fourier transformation, filtering, zero-filling, and phasing. The localized spectra can be subsequently presented for visualization or further processed to produce quantitative metabolite information. The presentation of the localized spectra in CSI is not a straightforward task because there can be thousands of spectra. In one-dimensional experiments, localized spectra are usually presented in a stack plot. In two-dimensional experiments, localized spectra are plotted in small boxes representing the extent of the pixels, and the plots can be overlaid on corresponding anatomic image for reference. Spectra from three-dimensional CSI experiments are usually presented slice by slice, each displaying the spectra as in the two-dimensional case.

To derive metabolite maps, peaks corresponding to the metabolites of interest need to be quantified. In principle, the peaks can be quantified using the standard methods developed for spectral quantification [15–17]. The most straightforward technique is to calculate the peak areas by integrating the spectra over the peak of interest if it does not overlap with other peaks significantly. In integrating all the localized spectra, spectral shift due to  $B_0$  inhomogeneity should be taken into account. A more robust approach is to apply spectral fitting programs to each spectrum to obtain various parameters of each peak. The fitted area for the peak of interest can then be used to represent the metabolite signal. The peak areas are then used to generate metabolite maps, which are images with intensities proportional to the localized peak area. The metabolite map can be displayed by itself as a gray-scale image or color-coded image or overlaid on a reference anatomic image.

### 12.4.2 Practical Examples

To illustrate the practical utility of CSI, we present two representative CSI studies in this section. The sequence for the first study is shown in Figure 12.21. This is a three-dimensional sequence in which phase encoding is applied in all three directions and no slice selection is used. Such a sequence is usually used with a surface RF coil whose spatial extent of sensitivity defines the field of view. In this sequence, the FID is acquired immediately after the application of the phase-encoding gradient to minimize the decay of the transverse magnetization, and the sequence is suitable for imaging metabolites with short transverse relaxation time (e.g., ATP).

With the sequence shown in Figure 12.21, a phosphorus-31 CSI study of the human brain was conducted using a quadrature surface coil. A nonselective RF pulse with an Ernst angle (40 degrees) optimized for the repetition time was used for the excitation. Phase-encoding gradients were applied for a duration of 500  $\mu$ sec; the phase-encoding gradients were incremented according to a FOV of  $25 \times 25 \times 20$  cm<sup>3</sup>. Phase-encoded FIDs were acquired with 1024 complex data points over a sampling window of 204.8 msec; the corresponding spectral width was 5000 Hz. To reduce intervoxel signal contamination, a technique that utilizes variable data averaging to introduce spatial filtering during the data acquisition for optimal signal-to-noise ratio is employed [7–10], resulting in spherical voxels with diameter of 3 cm (15 cc volume). The data were acquired with a  $TR$  of 1 sec, and the total acquisition time was approximately 28 min.

The acquired data were processed to generate three-dimensional voxels, each containing a localized phosphorus spectrum, in a  $17 \times 13 \times 17$  matrix. In Figure 12.22a–c, spectra in three slices of the three-dimensional CSI are presented; these spectra are overlaid on the corresponding anatomic images obtained with a  $T_1$ -weighted imaging sequence. One representative spectrum of the brain is illustrated in Figure 12.22d, where the peaks corresponding to various metabolites are labeled. It is evident that the localized phosphorus spectra contain a wealth of information about several metabolites of interest, including adenosine triphosphate (ATP), phosphocreatine (PCr), phosphomonoester (PME), inorganic phosphate ( $P_i$ ), and phosphodiester (PDE). In pathologic cases, focal abnormalities

**FIGURE 12.21** Sequence diagram for a three-dimensional chemical shift imaging sequence using a nonselective RF pulse.

in phosphorus metabolites have been detected in patients with tumor, epilepsy, and other diseases [18–25].

The second study described below is performed with the sequence depicted in Figure 12.23. This is a two-dimensional spin-echo sequence in which a slice is selectively excited by a 90-degree excitation pulse. The 180-degree refocusing pulse is selective with a slightly broader slice profile. Here the phase-encoding gradients are applied before the refocusing pulse; they also can be placed after the 180-degree pulse or split to both sides of the 180-degree pulse. This sequence was used for a proton CSI experiment. In proton CSI, a major problem arises from the strong water signal that overwhelms that of the metabolites. In order to suppress the water signal, many techniques have been devised [26–29]. In this study, a three-pulse CHESSE [26] technique was applied before the application of the excitation pulse as shown in Figure 12.23. The CSI experiment was performed on a 1.4-cm slice with  $32 \times 32$  phase encodings over a  $22 \times 22$  cm<sup>2</sup> FOV. The second half of the spin-echo was acquired with 512 complex data points over a sampling window of 256 msec, corresponding to a spectral width of 2000 Hz. Each phase-encoding FID was acquired twice for data averaging. The repetition time ( $TR$ ) and the echo time ( $TE$ ) used were 1.2 sec and 136 msec, respectively. The total acquisition time was approximately 40 min.

Another major problem in proton CSI study of the brain is that the signal from the subcutaneous lipid usually is much stronger than those of the metabolites, and this strong signal leaks into pixels within the brain due to truncation artifacts. To avoid lipid signal contamination, many proton CSI studies of the brain are performed within a selected region of interest excluding the subcutaneous fat [30–34]. Recently, several techniques have been proposed to suppress the lipid signal and consequently suppress the lipid signal contamination. These include the use of WEFT [27] and the use of outer-volume signal suppression [34]. In the example described below, we used a technique that utilizes the spatial location of the lipid to extrapolate data in the  $k$ -space to reduce the signal contamination due to truncation [35].

In Figure 12.24, the results from the proton CSI study are presented. In panel (a), the localized spectra are displayed. Note that the spectra in the subcutaneous lipid are ignored because they are all off the scale. The nominal spatial resolution is approximately 0.66 cc. A spectrum from an individual pixel in this study is presented in Figure 12.24b with metabolite peaks indicated. Several metabolite peaks, such as those corresponding to the *N*-acetyl aspartate (NAA), creatine/phosphocreatine (Cr/PCr), and choline (Cho), are readily identified. In addition, there is still a noticeable amount of residual lipid signal contamination

despite the use of the data extrapolation technique. Without the lipid suppression technique, the brain spectra would be severely contaminated by the lipid signal, making the detection of the metabolite peaks formidable. The peak of NAA in these spectra is fitted to generate the metabolite map shown in panel (c). Although the metabolite map is not corrected for coil sensitivity and other factors and only provides a relative measure of the metabolite concentration in the brain, it is a reasonable measure of the NAA distribution in the brain slice. The spatial resolution of the CSI study can be appreciated from the brain structure present in the map. In biomedical research, proton CSI is potentially the most promising technique, since it provides best sensitivity and spatial resolution. Various *in vivo* applications of proton spectroscopy can be found in the literature [36].

**FIGURE 12.22** (a)–(c) Boxed plot of spectra in three slices from the three-dimensional  $^{31}\text{P}$  CSI experiment overlaid on corresponding anatomic images. The spectral extent displayed is from 10 to 20 ppm. A 20-Hz line broadening is applied to all the spectra.

FIGURE 12.22 (d) Representative spectrum from the three-dimensional  $^{31}\text{P}$  CSI shown in (b). Metabolite peaks are labeled.

FIGURE 12.23 A two-dimensional spin-echo CSI sequence with chemical selective water suppression (CHESS) for proton study.

**FIGURE 12.24** (a) Boxed plot of spectra for the two-dimensional proton study overlaid on the anatomic image. A spectral range of 1.7 to 3.5 ppm is used in the plot to show Cho, PCr/Cr, and NAA. A 5-Hz line broadening is applied in the spectral processing. (b) A representative spectrum from the two-dimensional CSI in panel (a). Peaks corresponding to Cho, PCr/Cr, and NAA are indicated. (c) A map of the area under the NAA peak obtained by spectral fitting. The anatomic image is presented along with the metabolite map for reference. The spatial resolution of the metabolite image can be appreciated from the similarities between the two images. The lipid suppression technique has successfully eliminated the signal contamination from the lipid in the skull.

### 12.4.3 Summary

CSI is a technique for generating localized spectra that provide a wealth of biochemical information that can be used to study the metabolic activity of living system and to detect disease associated biochemical changes. This section provides an introduction to the technique and illustrates it by two representative examples. More specific topics concerning various aspects of CSI can be found in the literature.

## Acknowledgments

The authors would like to thank Dr. Xiao-Hong Zhu for assisting data acquisition and Mr. Gregory Adriany for hardware support. The studies presented here are supported by the National Institute of Health (RR08079).

*Barbara Y. Croft*

Nuclear medicine can be defined as the practice of making patients radioactive for diagnostic and therapeutic purposes. The radioactivity is injected intravenously, rebreathed, or ingested. It is the internal circulation of radioactive material that distinguishes nuclear medicine from diagnostic radiology and radiation oncology in most of its forms. This section will examine only the diagnostic use and will concentrate on methods for detecting the radioactivity from outside the body without trauma to the patient. Diagnostic nuclear medicine is successful for two main reasons (1) It can rely on the use of very small amounts of materials (picomolar concentrations in chemical terms) thus usually not having any effect on the processes being studied, and (2) the radionuclides being used can penetrate tissue and be detected outside the patient. Thus the materials can trace processes or “opacify” organs without affecting their function.

#### 13.1.1 Parameters for Choices in Nuclear Medicine

Of the various kinds of emanations from radioactive materials, photons alone have a range in tissue great enough to escape so that they can be detected externally. Electrons or beta-minus particles of high energy can create bremsstrahlung in interactions with tissue, but the radiation emanates from the site of the interaction, not the site of the beta ray’s production. Positrons or beta-plus particles annihilate with electrons to create gamma rays so that they can be detected (see Chapter 16). For certain radionuclides, the emanation being detected is x-rays, in the 50- to 100-keV energy range.

**TABLE 13.1** Gamma Ray Detection

Type of sample	Activity ( $\mu\text{Ci}$ )	Energy (keV)	Type of instrument
Patient samples, for example, blood, urine	0.001	0–5000	Gamma counter with annular NaI(Tl) detector, 1 or 2 PMTs, external Pb shielding
Small organ function <30 cm field of view at 60 cm distance	5–200	20–1500	2–4-in. NaI(Tl) detector with flared Pb collimator
Static image of body part, for example, liver, lung	0.2–30	50–650	Rectilinear scanner with focused Pb collimator
Dynamic image of body part, for example, xenon in airways	2–30	80–300	Anger camera and parallel-hole Pb collimator
Static tomographic image of body part	See Section 13.1		

The half-lives of materials in use in nuclear medicine range from a few minutes to weeks. The half-life must be chosen with two major points in mind: the time course of the process being studied and the radiation dose to the target organ, that is, that organ with the highest concentration over the longest time (the cumulated activity or area underneath the activity versus time curve). In general, it is desired to stay under **5 rad** to the target organ.

The choice of the best energy range to use is also based on two major criteria: the energy that will penetrate tissue but can be channeled by heavy metal shielding and collimation and that which will interact in the detector to produce a pulse. Thus the ideal energy is dependent on the detector being used and the kind of examination being performed. Table 13.1 describes the kinds of gamma-ray detection, the activity and energy ranges, and an example of the kind of information to be gained. The lesser amounts of activity are used in situations of lesser spatial resolution and of greater sensitivity. Positron imaging is omitted because it is treated elsewhere.

Radiation dose is affected by all the emanations of a radionuclide, not just the desirable ones, thus constricting the choice of nuclide further. There can be no alpha radiation used in diagnosis; the use of materials with primary beta radiation should be avoided because the beta radiation confers a radiation dose without adding to the information being gained. For imaging, in addition, even if there is a primary gamma ray in the correct energy window for the detector, there should be no large amount of radiation, either of primary radiation of higher energy, because it interferes with the image collimation, or of secondary radiation of a very similar energy, because it interferes with the perception of the primary radiation emanating from the site of interest.

For imaging using heavy-metal collimation, the energy range is constrained to be that which will emanate from the human body and which the collimation can contain, or about 50 to 500 keV.

Detectors must be made from materials that exhibit some detectable change when ionizing radiation is absorbed and that are of a high enough atomic number and density to make possible stopping large percentages of those gamma rays emanating (high sensitivity). In addition, because the primary gamma rays are not the only rays emanating from the source — a human body and therefore a distributed source accompanied by an absorber — there must be energy discrimination in the instrument to prevent the formation of an image of the scattered radiation. To achieve pulse size proportional to energy, and therefore to achieve identification of the energy and source of the energy, the detector must be a proportional detector. This means that Geiger-Muller detection, operating in an all-or-none fashion, is not acceptable.

Gaseous detectors are not practical because their density is not great enough. Liquid detectors (in which any component is liquid) are not practical because the liquid can spill when the detector is positioned; this problem can be compensated for if absolutely necessary, but it is better to consider it from the outset. Another property of a good detector is its ability to detect large numbers of gamma rays per time unit. With detection capabilities to separate 100,000 counts per second or a dead time of 2 msec, the system is still only detecting perhaps 1,000 counts per square centimeter per second over a  $10 \times 10$  cm area. The precision of the information is governed by **Poisson statistics**, so the imprecision in information collected

for 1 sec in a square centimeter is  $\pm 3\%$  at the 1 standard deviation level. Since we would hope for better spatial resolution than  $1 \text{ cm}^2$ , the precision is obviously worse than this. This points to the need for fast detectors, in addition to the aforementioned sensitivity. The more detector that surrounds the patient, the more sensitive the system will be. Table 13.2 lists in order from least sensitive to most sensitive some of the geometries used for imaging in nuclear medicine. This generally is also a listing from the older methods to the more recent.

For the purposes of this section, we shall consider that the problems of counting patient and other samples and of detecting the time course of activity changes in extended areas with probes are not our topic and confine ourselves to the attempts made to image distributions of gamma-emitting radionuclides in patients and research subjects. The previous section treats the three-dimensional imaging of these distributions; this section will treat detection of the distribution in a planar fashion or the image of the projection of the distribution onto a planar detector.

### 13.1.2 Detection of Photon Radiation

Gamma rays are detected when atoms in a detector are ionized and the ions are collected either directly as in gaseous or semiconductor systems or by first conversion of the ionized electrons to light and subsequent conversion of the light to electrons in a photomultiplier tube (P-M tube or PMT). In all cases there is a voltage applied across some distance that causes a pulse to be created when a photon is absorbed.

The gamma rays are emitted according to Poisson statistics because each decaying nucleus is independent of the others and has an equal probability of decaying per unit time. Because the uncertainty in the production of gamma rays is therefore on the order of magnitude of the square root of the number of gamma rays, the more gamma rays that are detected, the less the proportional uncertainty will be. Thus sensitivity is a very important issue for the creation of images, since the rays will be detected by area. To get better resolution, one must have the numbers of counts and the apparatus to resolve them spatially. Having the large numbers of counts also means the apparatus must resolve them temporally.

The need for **energy resolution** carries its own burden. Depending on the detector, the energy resolution may be easily achieved or not (Table 13.3). In any case, the attenuation and scattering inside the body means that there will be a range of gamma rays emitted, and it will be difficult to tell those scattered through very small angles from those not scattered at all. This affects the spatial resolution of the instrument.

The current practice of nuclear medicine has defined the limits of the amount of activity that can be administered to a patient by the amount of radiation dose. Since planar imaging with one detector allows only 2 pi detection at best and generally a view of somewhat less because the source is in the patient and the lead collimation means that only rays that are directed from the decay toward the crystal will be detected, it is of utmost importance to detect every ray possible. To the extent that no one is ever satisfied with the resolution of any system and always wishes for better, there is the need to be able to get spatial resolution better than the intrinsic 2 mm currently achievable. Some better collimation system, such as envisioned in a coincidence detection system like that used in PET, might make it possible to avoid stopping so many of the rays with the collimator.

We have now seen that energy resolution, sensitivity and resolving time of the detector are all bound up together to produce the spatial resolution of the instrument as well as the more obvious temporal

---

resolution. The need to collimate to create an image rather than a blush greatly decreases the numbers of counts and makes Poisson statistics a major determinant of the appearance of nuclear medical images.

Table 13.4 shows a calculation for the NaI(Tl)-based Anger camera showing 0.06% efficiency for the detection system. Thus the number of counts per second is not high and so is well within the temporal resolving capabilities of the detector system. The problem is the 0.06% efficiency, which is the effect of both the crystal thickness being optimized for imaging rather than for stopping all the gamma rays, and the lead collimation. Improvements in nuclear medicine imaging resolution can only come if both these factors are addressed.

### 13.1.3 Various Detector Configurations

The detectors in clinical nuclear medicine are NaI(Tl) crystals. In research applications, other substances are employed, but the engineering considerations for the use of other detectors are more complex and have been less thoroughly explored (Table 13.3).

The possibilities for configuring the detectors have been increasing, although the older methods tend to be discarded as the new ones are exploited (see Table 13.2). This is in part because each laboratory cannot afford to have one of every kind of instrument, although there are tasks for which each one is ideally suited.

The first instruments possible for plane-projection imaging consisted of a moving single crystal probe, called a rectilinear scanner. The probe consisted of a detector (beginning with NaI(Tl) but later incorporating small semiconductors) that was collimated by a focused lead collimator of appreciable thickness (often 2 in. of lead or more) with hole sizes and thicknesses of septa consonant with the intended energy and organ size and depth to be imaged. The collimated detector was caused to move across the patient at a constant speed; the pulses from the detector were converted to visible signals either by virtue of markings on a sheet or of light flashes exposing a film. This detector could see only one spot at a time, so only slow

**FIGURE 13.1** The Bender-Blau autofluoroscope is a multicrystal imager with a rectangular array of crystals connected to PMTs by plastic light guides. There is a PMT for each row of crystals and a PMT for each column of crystals, so an  $N$  by  $M$  array would have  $(N + M)$  PMTs.

temporal changes in activity could be appreciated. A small organ such as the thyroid could be imaged in this fashion very satisfactorily. Bone imaging also could be done with the later versions of this instrument.

To enlarge the size of the detector, several probes, each with its own photomultiplier tube and collimator, could be used. Versions of this idea were used to create dual-probe instruments to image both sides of the patient simultaneously, bars of probes to sweep down the patient and create a combined image, etc.

To go further with the multiple crystals to create yet larger fields of view, the autofluoroscope (Figure 13.1) combined crystals in a rectangular array. For each to have its own photomultiplier tube required too many PMTs, so the instrument was designed with a light pipe to connect each crystal with a PMT to indicate its row and a second one to indicate its column. The crystals are separated by lead septa to prevent scattered photons from one crystal affecting the next. Because of the large number of crystals and PMTs, the instrument is very fast, but because of the size of the crystals, the resolution is coarse. To improve the resolution, the collimator is often jittered so that each crystal is made to see more than one field of view to create a better resolved image. For those dynamic examinations in which temporal resolution is more important than spatial resolution, the system has a clear advantage. It has not been very popular for general use, however. In its commercial realization, the field of view was not large enough to image either lungs or livers or bones in any single image fashion.

As large NaI(Tl) crystals became a reality, new ways to use them were conceived. The Anger camera (Figure 13.2) is one of the older of these methods. The idea is to use a single crystal of diameter large enough to image a significant part of the human body and to back the crystal by an array of photomultiplier tubes to give positional sensitivity. Each PMT is assigned coordinates (Figure 13.3). When a photon is absorbed by the crystal, a number of PMTs receive light and therefore emit signals. The  $X$  and  $Y$  signal values for the emanation are determined by the strength of the signal from each of the tubes and its  $x$  and

**FIGURE 13.2** Anger camera detector design. This figure shows a cross section through the camera head. The active surface is pointed down. Shielding surrounds the assembly on the sides and top.

**FIGURE 13.3** An array of PMTs in the Anger camera showing the geometric connection between the PMTs and the X and Y output.

y position, and the energy of the emanation (which determines if it will be used to create the image) is the sum of all the signals (the Z pulse). If the discriminator passes the Z pulse, then the X and Y signals are sent to whatever device is recording the image, be it an oscilloscope and film recording system or the analog-to-digital (A/D) converters of a computer system. More recently, the A/D conversion is done earlier in the system so that the X and Y signals are themselves digital. The Anger camera is the major instrument in use in nuclear medicine today. It has been optimized for use with the 140-keV radiation from Tc-99m, although collimators have been designed for lower and higher energies, as well as optimized for higher sensitivity and higher resolution. The early systems used circular crystals, while the current configuration is likely to be rectangular or square.

A combination of the Anger positional logic and the focused collimator in a scanner produced the PhoCon instrument, which, because of the design of its collimators, had planar tomographic capabilities (the instrument could partially resolve activity in different planes, parallel to the direction of movement of the detector).

### 13.1.4 Ancillary Electronic Equipment for Detection

The detectors used in nuclear medicine are attached to preamplifiers, amplifiers, and pulse shapers to form a signal that can be examined for information about the energy of the detected photon (Figure 13.4). The energy discriminator has lower and upper windows that are set with reference radionuclides so that typically the particular nuclide in use can be dialed in along with the width of the energy window. A photon with an energy that falls in the selected range will cause the creation of a pulse of a voltage that falls in between the levels; all other photon energies will cause voltages either too high or too low. If only gross features are being recorded, any of the instruments may be used as probe detectors and the results recorded on strip-chart recordings of activity vs. time.

The PMT “multiplies” photons (Figure 13.5) because it has a quartz entrance window which is coated to release electrons when it absorbs a light photon and there is a voltage drop; the number of electrons

FIGURE 13.4 Schematic drawing of a generalized detector system. There would be a high-voltage power supply for the detector in an NaI(Tl)-PMT detector system.

FIGURE 13.5 Schematic drawing of a photomultiplier tube (PMT). Each of the dynodes and the anode is connected to a separate pin in the tube socket. The inside of the tube is evacuated of all gas. Dynodes are typically copper with a special oxidized coating for electron multiplication.

released is proportional to the amount of light that hits the coating. The electrons are guided through a hole and caused to hit the first dynode, which is coated with a special substance to allow it to release electrons when it is hit by an electron. There are a series of dynodes each with a voltage that pulls the electrons from the last dynodes toward it. The surface coating not only releases electrons but also multiplies the electron shower. In a cascade through 10–12 dynodes, there is a multiplication of approximately 106, so that pulses of a few electrons become currents of the order of 10–12 A. The PMTs must be protected from other influences, such as stray radioactivity or strong magnetic fields, which might cause extraneous electron formation or curves in the electron path. Without the voltage drop from one dynode to the next, there is no cascade of electrons and no counting.

For imaging, the  $x$  and  $y$  positions of those photons in the correct energy range will be recorded in the image because they have a  $Z$  pulse. Once the pulse has been accepted and the position determined, that position may be recorded to make an image either in analog or digital fashion; a spot may be made on an oscilloscope screen and recorded on film or paper, or the position may be digitized and stored in a computer file for later imaging on an oscilloscope screen and/or for photography. In general, the computers required are very similar to those used for other imaging modalities, except for the hardware that allows the acceptance of the pulse. The software is usually specifically created for nuclear medicine because of the unique needs for determination of function.

The calibration of the systems follows a similar pattern, no matter how simple or complex the instrument. Most probe detectors must be “peaked,” which means that the energy of the radioactivity must be connected with some setting of the instrument, often meant to read in kiloelectronvolts. This is accomplished by counting a sample with the instrument, using a reasonably narrow energy window, while varying the high voltage until the count rate reading is a maximum. The window is then widened for counting samples to encompass all the energy peak being counted. The detector is said to be linear if it can be set with one energy and another energy can be found where it should be on the kiloelectronvolt scale.

To ensure that the images of the radioactivity accurately depict the distribution in the object being imaged, the system must be initialized correctly and tested at intervals. The several properties that must be calibrated and corrected are sensitivity, uniformity, energy pulse shape, and linearity.

These issues are addressed in several ways. The first is that all the PMTs used in an imaging system must be chosen to have matched sensitivities and energy spectra. Next, during manufacture, and at intervals during maintenance, the PMTs’ response to voltage is matched so that the voltage from the power supply causes all the tubes to have maximum counts at the same voltage. The sensitivities of all the tubes are also matched during periodic maintenance. Prior to operation, usually at the start of each working day, the user will check the radioactive peak and then present the instrument with a source of activity to give an even exposure over the whole crystal. This uniform “flood” is recorded. The image may be used by the instrument for calibration; recalibration is usually performed at weekly intervals. The number of counts needed depends on the use the instrument is to be put to, but generally the instrument must be tested and calibrated with numbers of counts at least equal to those being emitted by the patients and other objects being imaged.

Because the PMT placement means that placement of the  $x$  and  $y$  locations is not perfect over the face of the crystal but has the effect of creating wiggly lines that may be closer together over the center of the PMT and farther apart at the interstices between tubes, the image may suffer from spatial nonlinearity. This can be corrected for by presenting the system with a lead pattern in straight-line bars or holes in rows and using a hard-wired or software method to position the  $X$  and  $Y$  signals correctly. This is called a linearity correction. In addition, there may be adjustments of the energy spectra of each tube to make them match each other so that variations in the number of kiloelectronvolts included in the window (created by varying the discriminator settings) will not create variations in sensitivity. This is called an energy correction.

### **13.1.5 Place of Planar Imaging in Nuclear Medicine Today: Applications and Economics**

There are various ways of thinking about diagnostic imaging and nuclear medicine. If the reason for imaging the patient is to determine the presence of disease, then there are at least two possible strategies. One is

to do the most complicated examination that will give a complete set of results on all patients. The other is to start with a simple examination and hope to categorize patients, perhaps into certain abnormal and all others, or even into abnormal, indeterminate, and normal. Then a subsequent, more complex examination is used to determine if there are more abnormal, or perhaps how abnormal they are. If the reason for imaging the patient is to collect a set of data that will be compared with results from that patient at a later time and with a range of normal results from all patients, then the least complex method possible for collecting the information should be used in a regular and routine fashion so that the comparison are possible.

In the former setting, where the complexity of the examination may have to be changed after the initial results are seen, in order to take full advantage of the dose of radioactive material that has been given to the patient, it is sensible to have the equipment available that will be able to perform the more complex examination and not to confine the equipment available to that capable of doing only the simple first examination. For this reason and because for some organs, such as the brain, the first examination is a SPECT examination, the new Anger cameras being sold today are mostly capable of doing rotating SPECT. The added necessities that SPECT brings to the instrument specifications are of degree: better stability, uniformity, and resolution. Thus they do not obviate the use of the equipment for planar imaging but rather enhance it. In the setting of performing only the examination necessary to define the disease, the Anger SPECT camera can be used for plane projection imaging and afterward for SPECT to further refine the examination. There are settings in which a planar camera will be purchased because of the simplicity of all the examinations (as in a very large laboratory that can have specialized instruments, a thyroid practice, or in the developing countries), but in the small- to medium-sized nuclear medicine practice, the new cameras being purchased are all SPECT-capable.

Nuclear medicine studies are generally less expensive than x-ray computed tomography or magnetic resonance imaging and more so than planar x-ray or ultrasound imaging. The general conduct of a nuclear medicine laboratory is more complex than these others because of the radioactive materials and the accompanying regulations. The specialty is practice both in clinics and in hospitals, but again, the complication imposed by the presence of the radioactive materials tips the balance of the practices toward the hospital. In that setting the practitioners may be imagers with a broad range of studies offered or cardiologists with a concentration on cardiac studies. Thus the setting also will determine what kind of instrument is most suitable.

## Defining Terms

**Energy resolution:** Full width at half maximum of graph of detected counts vs. energy, expressed as a percentage of the energy.

**Poisson statistics:** Expresses probability in situations of equal probability for an event per unit of time, such as radioactive decay or cosmic-ray appearance. The standard deviation of a mean number of counts is the square root of the mean number of counts, which is a decreasing fraction of the number of counts when expressed as a fraction of the number of counts.

**rad:** The unit of radiation energy absorption (dose) in matter, defined as the absorption of 100 ergs per gram of irradiated material. The unit is being replaced by the gray, an SI unit, where  $1 \text{ gray (Gy)} = 100 \text{ rad}$ .

## Further Information

A good introduction to nuclear medicine, written as a text for technologists, is *Nuclear Medicine Technology and Techniques*, edited by D.R. Bernier, J.K. Langan, and L.D. Wells. A treatment of many of the nuclear medicine physics issues is given in L.E. Williams' *Nuclear Medicine Physics*, published in three volumes. Journals that publish nuclear medicine articles include the monthly *Journal of Nuclear Medicine*, the *European Journal of Nuclear Medicine*, *Clinical Nuclear Medicine*, *IEEE Transactions in Nuclear Science*, *IEEE Transactions in Medical Imaging*, and *Medical Physics*. Quarterly and annual publications include *Seminars in Nuclear Medicine*, *Yearbook of Nuclear Medicine*, and *Nuclear Medicine Annual*.

The Society of Nuclear Medicine holds an annual scientific meeting that includes scientific papers, continuing education which could give the novice a broad introduction, poster sessions, and a large equipment exhibition. Another large meeting, devoted to many radiologic specialties is the Radiologic Society of North America's annual meeting, held just after Thanksgiving.

## 13.2 SPECT (Single-Photon Emission Computed Tomography)

---

*Benjamin M.W. Tsui*

During the last three decades, there has been much excitement in the development of diagnostic radiology. The development is fueled by inventions and advances made in a number of exciting new medical imaging modalities, including ultrasound (US), x-ray CT (computed tomography), PET (positron emission tomography), SPECT (single-photon emission computed tomography), and MRI (magnetic resonance imaging). These new imaging modalities have revolutionized the practice of diagnostic radiology, resulting in substantial improvement in patient care.

Single-photon emission computed tomography (SPECT) is a medical imaging modality that combines conventional nuclear medicine (NM) imaging techniques and CT methods. Different from x-ray CT, SPECT uses radioactive-labeled pharmaceuticals, that is, radiopharmaceuticals, that distribute in different internal tissues or organs instead of an external x-ray source. The spatial and uptake distributions of the radiopharmaceuticals depend on the biokinetic properties of the pharmaceuticals and the normal or abnormal state of the patient. The gamma photons emitted from the radioactive source are detected by radiation detectors similar to those used in conventional nuclear medicine. The CT method requires projection (or planar) image data to be acquired from different views around the patient. These projection data are subsequently reconstructed using image reconstruction methods that generate cross-sectional images of the internally distributed radiopharmaceuticals. The SPECT images provide much improved contrast and detailed information about the radiopharmaceutical distribution as compared with the planar images obtained from conventional nuclear medicine methods.

As an emission computed tomographic (ECT) method, SPECT differs from PET in the types of radionuclides used. PET uses radionuclides such as C-11, N-13, O-15, and F-18 that emit positrons with subsequent emission of two coincident 511 keV annihilation photons. These radionuclides allow studies of biophysiologic functions that cannot be obtained from other means. However, they have very short half-lives, often requiring an on-site cyclotron for their production. Also, detection of the annihilation photons requires expensive imaging systems. SPECT uses standard radionuclides normally found in nuclear medicine clinics and which emit individual gamma-ray photons with energies that are much lower than 511 keV. Typical examples are the 140-keV photons from Tc-99m and the ~70-keV photons from Tl-201. Subsequently, the costs of SPECT instrumentation and of performing SPECT are substantially less than PET.

Furthermore, substantial advances have been made in the development of new radiopharmaceuticals, instrumentation, and image processing and reconstruction methods for SPECT. The results are much improved quality and quantitative accuracy of SPECT images. These advances, combined with the relatively lower costs, have propelled SPECT to become an increasingly more important diagnostic tool in nuclear medicine clinics.

This section will present the basic principles of SPECT and the instrumentation and image processing and reconstruction methods that are necessary to reconstruct SPECT images. Finally, recent advances and future development that will continue to improve the diagnostic capability of SPECT will be discussed.

### 13.2.1 Basic Principles of SPECT

Single-photon emission computed tomography (SPECT) is a medical imaging technique that is based on the conventional nuclear medicine imaging technique and tomographic reconstruction methods. General review of the basic principles, instrumentation, and reconstruction technique for SPECT can be found in

**FIGURE 13.6** The conventional nuclear medicine imaging process. Gamma-ray photons emitted from the internally distributed radioactivity may experience photoelectric (a) or scatter (b) interactions. Photons that are not traveling in the direction within the acceptance analog of the collimator (c) will be intercepted by the lead collimator. Photons that experience no interaction and travel within the acceptance angle of the collimator will be detected (d).

a few review articles [Jaszczak et al., 1980; Jaszczak and Coleman, 1985a; Barrett, 1986; Jaszczak and Tsui, 1994].

### 13.2.1.1 The SPECT Imaging Process

The imaging process of SPECT can be simply depicted as in Figure 13.6. Gamma-ray photons emitted from the internal distributed radiopharmaceutical penetrate through the patient's body and are detected by a single or a set of collimated radiation detectors. The emitted photons experience interactions with the intervening tissues through basic interactions of radiation with matter [Evans, 1955]. The photoelectric effect absorbs all the energy of the photons and stops their emergence from the patient's body. The other major interaction is Compton interaction, which transfers part of the photon energy to free electrons. The original photon is scattered into a new direction with reduced energy that is dependent on the scatter angle. Photons that escape from the patient's body include those that have not experienced any interactions and those which have experienced Compton scattering. For the primary photons from the commonly used radionuclides in SPECT, for example, 140-keV of TC-99m and ~70-keV of TI-201, the probability of pair production is zero.

Most of the radiation detectors used in current SPECT systems are based on a single or multiple NaI(Tl) scintillation detectors. The most significant development in nuclear medicine is the scintillation camera (or Anger camera) that is based on a large-area (typically 40 cm in diameter) NaI(Tl) crystal [Anger, 1958, 1964]. An array of photomultiplier tubes (PMTs) is placed at the back of the scintillation crystal. When a photon hits and interacts with the crystal, the scintillation generated will be detected by the array of PMTs. An electronic circuitry evaluates the relative signals from the PMTs and determines the location of interaction of the incident photon in the scintillation crystal. In addition, the scintillation cameras have built-in energy discrimination electronic circuitry with finite energy resolution that provides selection of the photons that have not been scattered or been scattered within a small scattered angle. The scintillation cameras are commonly used in commercial SPECT systems.

Analogous to the lens in an optical imaging system, a scintillation camera system consists of a collimator placed in front of the NaI(Tl) crystal for the imaging purpose. The commonly used collimator is made of a large number of parallel holes separated by lead septa [Anger, 1964; Keller, 1968; Tsui, 1988]. The geometric dimensions, that is, length, size, and shape of the collimator apertures, determine the directions of photons that will be detected by the scintillation crystals or the geometric response of the collimator.

The width of the geometric response function increases (or the spatial resolution worsens) as the source distance from the collimator increases. Photons that do not pass through the collimator holes properly will be intercepted and absorbed by the lead septal walls of the collimator. In general, the detection efficiency is approximately proportional to the square of the width of the geometric response function of the collimator. This tradeoff between detection efficiency and spatial resolution is a fundamental property of a typical SPECT system using conventional collimators.

The amount of radioactivity that is used in SPECT is restricted by the allowable radiation dose to the patient. Combined with photon attenuation within the patient, the practical limit on imaging time, and the tradeoff between detection efficiency and spatial resolution of the collimator, the number of photons that are collected by a SPECT system is limited. These limitations resulted in SPECT images with relatively poor spatial resolution and high statistical noise fluctuations as compared with other medical imaging modalities. For example, currently a typical brain SPECT image has a total of about 500K counts per image slice and a spatial resolution in the order of approximately 8 mm. A typical myocardial SPECT study using TI-201 has about 150K total count per image slice and a spatial resolution of approximately 15 mm.

In SPECT, projection data are acquired from different views around the patient. Similar to x-ray CT, image processing and reconstruction methods are used to obtain transaxial or cross-sectional images from the multiple projection data. These methods consist of preprocessing and calibration procedures before further processing, mathematical algorithms for reconstruction from projections, and compensation methods for image degradation due to photon attenuation, scatter, and detector response.

The biokinetics of the radiopharmaceutical used, anatomy of the patient, instrumentation for data acquisition, preprocessing methods, image reconstruction techniques, and compensation methods have important effects on the quality and quantitative accuracy of the final SPECT images. A full understanding of SPECT cannot be accomplished without clear understanding of these factors. The biokinetics of radiopharmaceuticals and conventional radiation detectors have been described in the previous section on conventional nuclear medicine. The following subsections will present the major physical factors that affect SPECT and a summary review of the instrumentation, image reconstruction techniques, and compensation methods that are important technological and engineering aspects in the practice of SPECT.

### 13.2.1.2 Physical and Instrumentation Factors that Affect SPECT Images

There are several important physical and instrumentation factors that affect the measured data and subsequently the SPECT images. The characteristics and effects of these factors can be found in a few review articles [Jaszczak et al., 1981; Jaszczak and Tsui, 1994; Tsui et al., 1994a, 1994b]. As described earlier, gamma-ray photons that emit from an internal source may experience photoelectric absorption within the patient without contributing to the acquired data, Compton scattering with change in direction and loss of energy, or no interaction before exiting the patient's body. The exiting photons will be further selected by the geometric response of the collimator-detector. The photoelectric and Compton interactions and the characteristics of the collimator-detector have significant effects on both the quality and quantitative accuracy of SPECT image.

Photon attenuation is defined as the effect due to photoelectric and Compton interactions resulting in a reduced number of photons that would have been detected without them. The degree of attenuation is determined by the linear attenuation coefficient, which is a function of photon energy and the amount and types of materials contained in the attenuating medium. For example, the attenuation coefficient for the 140-keV photon emitted from the commonly used Tc-99m in water or soft tissue is  $0.15 \text{ cm}^{-1}$ . This gives rise to a half-valued-layer, the thickness of material that attenuates half the incident photons, or 4.5 cm H<sub>2</sub>O for the 140-keV photon. Attenuation is the most important factor that affects the quantitative accuracy of SPECT images.

Attenuation effect is complicated by the fact that within the patient the attenuation coefficient can be quite different in various organs. The effect is most prominent in the thorax, where the attenuation coefficients range from as low as  $0.05 \text{ cm}^{-1}$  in the lung to as high as  $0.18 \text{ cm}^{-1}$  in the compact bone for the 140-keV photons. In x-ray CT, the attenuation coefficient distribution is the target for image reconstruction. In SPECT, however, the wide range of attenuation coefficient values and the variations

of attenuation coefficient distributions among patients are major difficulties in obtaining quantitative accurate SPECT images. Therefore, compensation for attenuation is important to ensure good image quality and quantitatively high accuracy in SPECT. Review of different attenuation methods that have been used in SPECT is a subject of discussion later in this chapter.

Photons that have been scattered before reaching the radiation detector provide misplaced spatial information about the origin of the radioactive source. The results are inaccurate quantitative information and poor contrast in the SPECT images. For radiation detectors with perfect energy discrimination, scattered photons can be completely rejected. In a typical scintillation camera system, however, the energy resolution is in the order of 10% at 140 keV. With this energy resolution, the ratio of scattered to scattered total photons detected by a typical scintillation detector is about 20–30% in brain and about 30–40% in cardiac and body SPECT studies for 140-keV photons. Furthermore, the effect of scatter depends on the distribution of the radiopharmaceutical, the proximity of the source organ to the target organ, and the energy window used in addition to the photon energy and the energy resolution of the scintillation detector. The compensation of scatter is another important aspect of SPECT to ensure good image quality and quantitative accuracy.

The advances in SPECT can be attributed to simultaneous development of new radiopharmaceuticals, instrumentation, reconstruction methods, and clinical applications. Most radiopharmaceuticals that are developed for conventional nuclear medicine can readily be used in SPECT, and review of these developments is beyond the scope of this chapter. Recent advances include new agents that are labeled with iodine and technetium for blood perfusion for brain and cardiac studies. Also, the use of receptor agents and labeled antibiotics is being investigated. These developments have resulted in radiopharmaceuticals with improved uptake distribution, biokinetics properties, and potentially new clinical applications. The following subsections will concentrate on the development of instrumentation and image reconstruction methods that have made substantial impact on SPECT.

## 13.2.2 SPECT Instrumentation

Review of the advances in SPECT instrumentation can be found in several recent articles [Jaszczak et al., 1980; Rogers and Ackermann, 1992; Jaszczak and Tsui, 1994]. A typical SPECT system consists of a single or multiple units of radiation detectors arranged in a specific geometric configuration and a mechanism for moving the radiation detector(s) or specially designed collimators to acquire data from different projection views. In general, SPECT instrumentation can be divided into three general categories (1) arrays of multiple scintillation detectors, (2) one or more scintillation cameras, and (3) hybrid scintillation detectors combining the first two approaches. In addition, special collimator designs have been proposed for SPECT for specific purposes and clinical applications. The following is a brief review of these SPECT systems and special collimators.

### 13.2.2.1 Multidetector SPECT System

The first fully functional SPECT imaging acquisition system was designed and constructed by Kuhl and Edwards [Kuhl and Edwards, 1963, 1964, 1968] in the 1960s, well before the conception of x-ray CT. As shown in Figure 13.7a, the MARK IV brain SPECT system consisted of four linear arrays of eight discrete NaI(Tl) scintillation detectors assembled in a square arrangement. Projection data were obtained by rotating the square detector array around the patient's head. Although images from the pioneer MARK IV SPECT system were unimpressive without the use of proper reconstruction methods that were developed in later years, the multidetector design has been the theme of several other SPECT systems that were developed. An example is the Gammatom-1 developed by Cho et al. [1982]. The design concept also was used in a dynamic SPECT system [Stokely et al., 1980] and commercial multidetector SPECT systems marketed by Medimatic, A/S (Tomomatic-32). Recently, the system design was extended to a multislice SPECT system with the Tomomatic-896, consisting of eight layers of 96 scintillation detectors. Also, the system allows both body and brain SPECT imaging by varying the aperture size.

**FIGURE 13.7** Examples of multidetector-based SPECT systems. (a) The MARK IV system consists of four arrays of eight individual NaI(Tl) detectors arranged in a square configuration. (b) The Headtome-II system consists of a circular ring of detectors. A set of collimator vanes that swings in front of the discrete detector is used to collect projection data from different views. (c) A unique Cleon brain SPECT system consists of 12 detectors that scan both radially and tangentially.

Variations of the multiple-detectors arrangement have been proposed for SPECT system designs. Figure 13.7b shows the Headtome-II system by Shimadzu Corporation [Hirose et al., 1982], which consists of a stationary array of scintillation detectors arranged in a circular ring. Projection data are obtained by a set of collimator vanes that swings in front of the discrete detectors. A unique Cleon brain SPECT system (see Figure 13.7c), originally developed by Union Carbide Corporation in the 1970s, consists of 12 detectors that scan both radially and tangentially [Stoddart and Stoddart, 1979]. Images from the original system were unimpressive due to inadequate sampling, poor axial resolution, and a reconstruction algorithm that did not take full advantage of the unique system design and data acquisition strategy. A much improved version of the system with a new reconstruction method [Moore et al., 1984] is currently marketed by Strichman Corporation.

The advantages of multidetector SPECT systems are their high sensitivity per image slice and high counting rate capability resulting from the array of multidetectors fully surrounding the patient. However, disadvantages of multidetector SPECT systems include their ability to provide only one or a few noncontiguous cross-sectional image slices. Also, these systems are relatively more expensive compared with camera-based SPECT systems described in the next section. With the advance of multicamera SPECT systems, the disadvantages of multidetector SPECT systems outweigh their advantages. As a result, they are less often found in nuclear medicine clinics.

### 13.2.2.2 Camera-Based SPECT Systems

The most popular SPECT systems are based on single or multiple scintillation cameras mounted on a rotating gantry. The successful design was developed almost simultaneously by three separate groups [Budinger and Gullberg, 1977; Jaszczak et al., 1977; Keyes et al., 1977]. In 1981, General Electric Medical Systems offered the first commercial SPECT system based on a single rotating camera and brought SPECT to clinical use. Today, there are over ten manufacturers (e.g., ADAC, Elscint, General Electric, Hitachi, Picker, Siemens, Sopher, Toshiba, Trionix) offering an array of commercial SPECT systems in the marketplace.

An advantage of camera-based SPECT systems is their use of off-the-shelf scintillation cameras that have been widely used in conventional nuclear medicine. These systems usually can be used in both conventional planar and SPECT imaging. Also, camera-based SPECT systems allow truly three-dimensional (3D) imaging by providing a large set of contiguous transaxial images that cover the entire organ of interest. They are easily adaptable for SPECT imaging of the brain or body by simply changing the radius of rotation of the camera.

A disadvantage of a camera-based SPECT system is its relatively low counting rate capability. The dead time of a typical state-of-the-art scintillation camera gives rise to a loss of 20% of its true counts at about 80K counts per second. A few special high-count-rate systems give the same count rate loss at about 150K

**FIGURE 13.8** Examples of camera-based SPECT systems. (a) Single-camera system. (b) Dual-camera system with the two cameras placed at opposing sides of patient during rotation. (c) Dual-camera system with the two cameras placed at right angles. (d) Triple-camera system. (e) Quadruple-camera system.

counts per second. For SPECT systems using a single scintillation camera, the sensitivity per image slice is relative low compared with a typical multidetector SPECT system.

Recently, SPECT systems based on multiple cameras became increasingly more popular. Systems with two [Jaszczak et al., 1979a], three [Lim et al., 1980, 1985], and four cameras provide increased sensitivity per image slice that is proportional to the number of cameras. Figure 13.8 shows the system configurations of these camera-based SPECT systems. The dual-camera systems with two opposing cameras (Figure 13.8b) can be used for both whole-body scanning and SPECT, and those with two right-angled cameras (Figure 13.8c) are especially useful for 180-degree acquisition in cardiac SPECT. The use of multicameras has virtually eliminated the disadvantages of camera-based SPECT systems as compared with multidetector SPECT systems. The detection efficiency of camera-based SPECT systems can be further increased by using converging-hole collimators such as fan, cone, and astigmatic collimators at the cost of a smaller field of view. The use of converging-hole collimators in SPECT will be described in a later section.

### 13.2.2.3 Novel SPECT System Designs

There are several special SPECT systems designs that do not fit into the preceding two general categories. The commercially available CERESPECT (formerly known as ASPECT) [Genna and Smith, 1988] is a dedicated brain SPECT system. As shown in Figure 13.9a, it consists of a single fixed-annular NaI(Tl) crystal that completely surrounds the patient's head. Similar to a scintillation camera, an array of PMTs and electronics circuitry are placed behind the crystal to provide positional and energy information about photons that interact with the crystal. Projection data are obtained by rotating a segmented annular collimator with parallel holes that fits inside the stationary detector. A similar system is also being developed by Larsson et al. [1991] in Sweden.

Several unique SPECT systems are currently being developed in research laboratories. They consist of modules of small scintillation cameras that surround the patient. The hybrid designs combine the advantage of multidetector and camera-based SPECT systems with added flexibility in system configuration. An example is the SPRINT II brain SPECT system developed at the University of Michigan [Rogers et al., 1988]. As shown in Figure 13.9b, the system consists of 11 detector modules arranged in a circular ring around the patient's head. Each detector module consists of 44 one-dimensional (1D) bar NaI(Tl) scintillation cameras. Projection data are required through a series of narrow slit openings on a rotating lead ring that fits inside the circular detector assemblies. A similar system was developed at the University of Iowa [Chang et al., 1990] with 22 detector modules, each consisting of four bar detectors. A set of rotating focused collimators is used to acquire projection data necessary for image reconstruction. At the University of Arizona, a novel SPECT system is being developed that consists of 20 small modular scintillation cameras [Milster et al., 1990] arranged in a hemispherical shell surrounding the patient's head [Rowe et al., 1992]. Projection data are acquired through a stationary hemispherical array of pinholes that are fitted inside the camera array. Without moving parts, the system allows acquisition of dynamic 3D SPECT data.

**FIGURE 13.9** Examples of novel SPECT system designs. (a) The CERESPECT brain SPECT system consists of a single fixed annular NaI(Tl) crystal and a rotating segmented annular collimator. (b) The SPRINT II brain SPECT system consists of 11 detector modules and a rotating lead ring with slit opening.

**FIGURE 13.10** Collimator designs used in camera-based SPECT systems. (a) The commonly used parallel-hole collimator. (b) The fan-beam collimator, where the collimator holes are converged to a line that is parallel to the axis of rotation. (c) The cone-beam collimator, where the collimator holes are converged to a point. (d) A varifocal collimator, where the collimator holes are converged to various focal points.

**13.2.2.4 Special Collimator Designs for SPECT Systems**

Similar to conventional nuclear medicine imaging, parallel-hole collimators (Figure 13.10a) are commonly used in camera-based SPECT systems. As described earlier, the tradeoff between detection efficiency and spatial resolution of parallel-hole collimator is a limiting factor for SPECT. A means to improve SPECT system performance is to improve the tradeoff imposed by the parallel-hole collimation.

To achieve this goal, converging-hole collimator designs that increase the angle of acceptance of incoming photons without sacrificing spatial resolution have been developed. Examples are fan-beam [Jaszczak et al., 1979b; Tsui et al., 1986], cone-beam [Jaszczak et al., 1987], astigmatic [Hawman and Hsieh, 1986], and more recently varifocal collimators. As shown in Figure 13.10b, the collimator holes converge to a line that is oriented parallel to the axis of rotation for a fan-beam collimator, to a point for a cone-beam collimator, and to various points for a varifocal collimator, respectively. The gain in detection efficiency of

a typical fan-beam and cone-beam collimator is about 1.5 and 2 times of that of a parallel-hole collimator with the same spatial resolution. The anticipated gain in detection efficiency and corresponding decrease in image noise are the main reasons for the interest in applying converging-hole collimators in SPECT.

Despite the advantage of increased detection efficiency, the use of converging-hole collimators in SPECT poses special problems. The tradeoff for increase in detection efficiency as compared with parallel-hole collimators is a decrease in field of view (see Figure 13.10). Consequently, converging-hole collimators are restricted to imaging small organs or body parts such as the head [Jaszczak et al., 1979b; Tsui et al., 1986] and heart [Gullberg et al., 1991]. In addition, the use of converging-hole collimators requires special data-acquisition strategies and image reconstruction algorithms. For example, for cone-beam tomography using a conventional single planar orbit, the acquired projection data become increasingly insufficient for reconstructing transaxial image sections that are further away from the central plane of the cone-beam geometry. Active research is underway to study special rotational orbits for sufficient projection data acquisition and 3D image reconstruction methods specific for cone-beam SPECT.

### 13.2.3 Reconstruction Methods

As discussed earlier, SPECT combines conventional nuclear medicine image techniques and methods for image reconstruction from projections. Aside from radiopharmaceuticals and instrumentation, image reconstruction methods are another important engineering and technological aspect of the SPECT imaging technique.

In x-ray CT, accurate transaxial images can be obtained through the use of standard algorithms for image reconstruction from projections. The results are images of attenuation coefficient distribution of various organs within the patient's body. In SPECT, the goal of image reconstruction is to determine the distribution of administered radiopharmaceutical in the patient. However, the presence of photon attenuation affects the measured projection data. If conventional reconstruction algorithms are used without proper compensation for the attenuation effects, inaccurate reconstructed images will be obtained. Effects of scatter and the finite collimator–detector response impose additional difficulties on image reconstruction in SPECT.

In order to achieve quantitatively accurate images, special reconstruction methods are required for SPECT. Quantitatively accurate image reconstruction methods for SPECT consist of two major components. They are the standard algorithms for image reconstruction from projections and methods that compensate for the image-degrading effects described earlier. Often, image reconstruction algorithms are inseparable from the compensation methods, resulting in a new breed of reconstruction method not found in other tomographic medical imaging modalities. The following sections will present the reconstruction problem and a brief review of conventional algorithms for image reconstruction from projections. Then quantitative SPECT reconstruction methods that include additional compensation methods will be described.

#### 13.2.3.1 Image Reconstruction Problem

Figure 13.11 shows a schematic diagram of the two-dimensional (2D) image reconstruction problem. Let  $f(x, y)$  represent a 2D object distribution that is to be determined. A 1D detector array is oriented at an angle  $q$  with respect to the  $x$ -axis of the laboratory coordinates system  $(x, y)$ . The data collected into each detector element at location  $t$ , called the projection data  $p(t, q)$ , is equal to the sum of  $f(x, y)$  along a ray that is perpendicular to the detector array and intersects the detector at position  $t$ ; that is,

$$p(t, \theta) = c \int_{-\alpha}^{\alpha} f(x, y) ds \quad (13.1)$$

where  $(s, t)$  represents a coordinate system with  $s$  along the direction of the ray sum and  $t$  parallel to the 1D detector array, and  $c$  is the gain factor of the detection system. The angle between the  $s$  and  $x$ -axes is  $\theta$ . The relationship between the source position  $(x, y)$ , the projection angle  $\theta$ , and the position of detection

**FIGURE 13.11** Schematic diagram of the two-dimensional image reconstruction problem. The projection data are line integrals of the object distribution along rays that are perpendicular to the detector. A source point  $(x, y)$  is projected onto a point  $p(t, \theta)$ , where  $t$  is a position along the projection and  $\theta$  is the projection angle.

on the 1D detector array is given by

$$t = y \cos \theta - x \sin \theta \tag{13.2}$$

In 2D tomographic imaging, the 1D detector array rotates around the object distribution  $f(x, y)$  and collects projection data from various projection angles  $\theta$ . The integral transform of the object distribution to its projections given by Equation 13.1 is called the Radon transform [Radon, 1917]. The goal of image reconstruction is to solve the inverse Radon transform. The solution is the reconstructed image estimate  $\hat{f}(x, y)$  of the object distribution  $f(x, y)$ .

In x-ray CT, the measured projection data is given by

$$p'(t, \theta) = c_1 I_0 \exp \left[ - \int_{-\alpha}^{+\alpha} \mu(x, y) ds \right] \tag{13.3}$$

where  $I_0$  is the intensity of the incident x-ray,  $\mu(x, y)$  is the 2D attenuation coefficient, and  $c_1$  is the gain factor which transforms x-ray intensity to detected signals. The reconstruction problem can be rewritten as

$$p(t, \theta) = \ln \left[ \frac{I_0}{p'(t, \theta)} \right] = \int_{-\alpha}^{+\alpha} \mu(x, y) ds \tag{13.4}$$

with the goal to solve for the attenuation coefficient distribution  $\mu(x, y)$ . Also, in x-ray CT, if parallel rays are used, the projection data at opposing views are the same, that is,  $p(t, \theta) = p(t, \theta + \pi)$ , and projection data acquired over 180 degrees will be sufficient for reconstruction. The number of linear samples along the 1D projection array and angular samples, that is, the number of projection views, over 180 degrees must be chosen carefully to avoid aliasing error and resolution loss in the reconstructed images.

In SPECT, if the effects of attenuation, scatter, and collimator–detector response are ignored, the measured projection data can be written as the integral of radioactivity along the projection rays; that is,

$$p(t, \theta) = c_e \int_{-\alpha}^{+\alpha} \rho(x, y) ds \tag{13.5}$$

where  $\rho(x, y)$  is the radioactivity concentration distribution of the object, and  $c_e$  is the gain factor which transforms radioactivity concentration to detected signals. Equation 13.5 fits in the form of the Radon transform, and similar to x-ray CT, the radioactivity distribution can be obtained by solving the inverse Radon transform problem.

If attenuation is taken into consideration, the attenuated Radon transform [Gullberg, 1979] can be written as

$$p(t, \theta_i) = c_e \int_{-\alpha}^{+\alpha} \rho(x, y) \exp \left[ - \int_{(x,y)}^{+\alpha} \mu(u, v) ds' \right] ds \quad (13.6)$$

where  $\mu(u, v)$  is the 2D attenuation coefficient distribution, and  $\int_{(x,y)}^{+\alpha} \mu(u, v) ds$  is the attenuation factor for photons that originate from  $(x, y)$ , travel along the direction perpendicular to the detector array, and are detected by the collimator–detector. A major difficulty in SPECT image reconstruction lies in the attenuation factor, which makes the inverse problem given by Equation 13.6 difficult to solve analytically. However, the solution is important in cardiac SPECT, where the widely different attenuation coefficients are found in various organs within the thorax. Also, due to the attenuation factor, the projection views at opposing angles are different. Hence full 360-degree projection data are usually necessary for image reconstruction in SPECT.

Different from x-ray CT, small differences in attenuation coefficient are not as important in SPECT. When the attenuation coefficient in the body region can be considered constant, the attenuated Radon transform given by Equation 13.6 can be written as [Tretiak and Metz, 1980]

$$p(t, \theta) = c_e \int_{-\alpha}^{+\alpha} \rho(x, y) \exp[-\mu l(x, y)] ds \quad (13.7)$$

where  $\mu$  is the constant attenuation coefficient in the body region, and  $l(x, y)$  is the path length between the point  $(x, y)$  and the edge of the attenuator (or patient's body) along the direction of the projection ray. The solution of the inverse problem with constant attenuator has been a subject of several investigations. It forms the basis for analytical methods for compensation of uniform attenuation described later in this chapter.

When scatter and collimator–detector response are taken into consideration, the assumption that the projection data can be represented by line integrals given by Equation 13.1 to Equation 13.7 will no longer be exactly correct. Instead, the integration will have to include a wider region covering the field of view of the collimator–detector (or the collimator–detector response function). The image reconstruction problem is further complicated by the nonstationary properties of the collimator–detector and scatter response functions and their dependence on the size and composition of the patient's body.

### 13.2.3.2 Algorithms for Image Reconstruction from Projections

The application of methods for image reconstruction from projections was a major component in the development of x-ray CT in the 1970s. The goal was to solve for the inverse Radon transform problem given in Equation 13.1. There is an extensive literature on these reconstruction algorithms. Reviews of the applications of these algorithms to SPECT can be found in several articles [Budinger and Gullberg, 1974; Brooks and Di Chiro, 1975, 1976; Barrett, 1986].

*Simple backprojection:* An intuitive image reconstruction method is simple backprojection. Here, the reconstructed image is formed simply by spreading the values of the measured projection data uniformly along the projection ray into the reconstructed image array. By backprojecting the measured projection data from all projection views, an estimate of the object distribution can be obtained. Mathematically,

the simple backproject operation is given by

$$\hat{f}(x, y) = \sum_{j=1}^m p(y \cos \theta_j - x \sin \theta_j, \theta_j) \Delta \theta \quad (13.8)$$

where  $\theta_j$  is the  $j$ th projection angle,  $m$  is the number of projection views, and  $\Delta \theta$  is the angular spacing between adjacent projections. The simple backprojected image  $\hat{f}(x, y)$  is a poor approximation of the true object distribution  $f(x, y)$ . It is equivalent to the true object distribution blurred by a blurring function in the form of  $1/r$ .

There are two approaches for accurate image reconstruction, and both have been applied to SPECT. The first approach is based on direct analytical methods and is widely used in commercial SPECT systems. The second approach is based on statistical criteria and iterative algorithms. They have been found useful in reconstruction methods that include compensation for the image-degrading effects.

*Analytical reconstruction algorithms: filtered backprojection:* The most widely used analytical image-reconstruction algorithm is the filtered backprojection (FBP) method, which involves backprojecting the filtered projections [Bracewell and Riddle, 1967; Ramachandran and Lakshminarayanan, 1971]. The algorithm consists of two major steps:

1. Filter the measured projection data at different projection angles with a special function
2. Backproject the filtered projection data to form the reconstructed image

The first step of the filtered backprojection method can be implemented in two different ways. In the spatial domain, the filter operation is equivalent to convolving the measured projection data using a special convolving function  $h(t)$ ; that is,

$$p'(t, \theta) = p(t, \theta) * h(t) \quad (13.8a)$$

where  $*$  is the convolution operation. With the advance of FFT methods, the convolution operation can be replaced by a more efficient multiplication in the spatial frequency domain. The equivalent operation consists of three steps:

1. Fourier-transform the measured projection data into spatial frequency domain using the FFT method, that is,  $P(v, \theta) = \text{FT}\{p(t, \theta)\}$ , where FT is the Fourier transform operation.
2. Multiply the Fourier-transformed projection data with a special function that is equal to the Fourier transform of the special function used in the convolution operation described above, that is,  $P'(v, \theta) = P(v, \theta) \cdot H(v)$ , where  $H(v) = \text{FT}\{h(x)\}$  is the Fourier transform of  $h(x)$ .
3. Inverse Fourier transform the product  $P'(v, \theta)$  into spatial domain.

Again, the filtered projections from different projection angles are backprojected to form the reconstructed images.

The solution of the inverse Radon transform given in Equation 13.1 specifies the form of the special function. In the spatial domain, the special function  $h(x)$  used in the convolution operation in Equation 13.8 is given by

$$h(x) = \frac{1}{2(\Delta x)^2} \left\{ \text{sinc} \left[ \frac{x}{(\Delta x)} \right] \right\} - \frac{1}{4(\Delta x)^2} \left\{ \text{sinc}^2 \left[ \frac{x}{2(\Delta x)} \right] \right\} \quad (13.9)$$

where  $\Delta x$  is the linear sampling interval, and  $\text{sinc}(z) = [\sin(z)]/z$ . The function  $h(x)$  consists of a narrow central peak with high magnitude and small negative side lobes. It removes the blurring from the  $1/r$  function found in the simple backprojected images.

In the frequency domain, the special function  $H(\nu)$  is equivalent to the Fourier transform of  $h(x)$  and is a truncated ramp function given by

$$H(\nu) = |\nu| \cdot \text{rect}(\nu) \quad (13.10)$$

where  $|\nu|$  is the ramp function, and

$$\text{rect}(\nu) = \begin{cases} 1, & |\nu| \leq 0.5 \\ 0, & \nu < 0.5 \end{cases} \quad (13.11)$$

that is, the rectangular function  $\text{rect}(\nu)$  has a value of 1 when the absolute value of  $\nu$  is less than the Nyquist frequency at 0.5 cycles per pixel.

For noisy projection data, the ramp function tends to amplify the high-frequency noise. In these situations, an additional smoothing filter is often applied to smoothly roll off the high-frequency response of the ramp function. Examples are Hann and Butterworth filters [Huesman et al., 1977]. Also, deconvolution filters have been used to provide partial compensation of spatial resolution loss due to the collimator-detection response and noise smoothing. Examples are the Metz and Wiener filters (see later).

*Iterative reconstruction algorithms:* Another approach to image reconstruction is based on statistical criteria and iterative algorithms. They were investigated for application in SPECT before the development of analytical image reconstruction methods [Kuhl and Edwards, 1968; Gordon et al., 1970; Gilbert, 1972; Goitein, 1972]. The major drawbacks of iterative reconstruction algorithms are the extensive computations and long processing time required. For these reasons, the analytical reconstruction methods have gained widespread acceptance in clinical SPECT systems. In recent years, there has been renewed interest in the use of iterative reconstruction algorithms in SPECT to achieve accurate quantitation by compensating for the image-degrading effects.

A typical iterative reconstruction algorithm starts with an initial estimate of the object source distribution. A set of projection data is estimated from the initial estimate using a projector that models the imaging process. The estimated projection data are compared with the measured projection data at the same projection angles, and their differences are calculated. Using an algorithm derived from specific statistical criteria, the differences are used to update the initial image estimate. The updated image estimate is then used to recalculate a new set of estimated projection data that are again compared with the measured projection data. The procedure is repeated until the difference between the estimated and measured projection data are smaller than a preselected small value. Statistical criteria that have been used in formulating iterative reconstruction algorithms include the minimum mean squares error (MMSE) [Budinger and Gullberg, 1977], weighted least squares (WLS) [Huesman et al., 1977], maximum entropy (ME) [Minerbo, 1979], maximum likelihood (ML) [Shepp and Vardi, 1982], and maximum a posteriori approaches [Geman and McClure, 1985; Barrett, 1986; Levitan and Herman, 1987; Liang and Hart, 1987; Johnson et al., 1991]. Iterative algorithms that have been used in estimating the reconstructed images include the conjugate gradient (CG) [Huesman et al., 1977] and expectation maximization (EM) [Lange and Carson, 1984].

Recently, interest in the application of iterative reconstruction algorithms in SPECT has been revitalized. The interest is sparked by the need to compensate for the spatially variant and/or nonstationary image-degrading factors in the SPECT imaging process. The compensation can be achieved by modeling the imaging process that includes the image-degrading factors in the projection and backprojection operations of the iterative steps. The development is aided by advances made in computer technology and custom-dedicated processors. The drawback of long processing time in using these algorithms is substantially reduced. Discussion of the application of iterative reconstruction algorithms in SPECT will be presented in a later section.

### 13.2.3.3 Compensation Methods

For a typical SPECT system, the measured projection data are severely affected by attenuation, scatter, and collimator–detector response. Direct reconstruction of the measured projection data without compensation of these effects produces images with artifacts, distortions, and inaccurate quantitation. In recent years, substantial efforts have been made to develop compensation methods for these image-degrading effects. This development has produced much improved quality and quantitatively accurate reconstructed images. The following sections will present a brief review of some of these compensation methods.

*Compensation for attenuation:* Methods for attenuation compensation can be grouped into two categories (1) methods that assume the attenuation coefficient is uniform over the body region, and (2) methods that address situations of nonuniform attenuation coefficient distribution. The assumption of uniform attenuation can be applied to SPECT imaging of the head and abdomen regions. The compensation methods seek to solve for the inverse of the attenuated Radon transform given in Equation 13.7. For cardiac and lung SPECT imaging, nonuniform attenuation compensation methods must be used due to the very different attenuation coefficient values in various organs in the thorax. Here, the goal is to solve the more complicated problem of the inverse of the attenuated Radon transform in Equation 13.6.

There are several approximate methods for compensating uniform attenuation. They include methods that preprocess the projection data or postprocess the reconstructed image. The typical preprocess methods are those which use the geometric or arithmetic mean [Sorenson, 1974] of projections from opposing views. These compensation methods are easy to implement and work well with a single, isolated source. However, they are relatively inaccurate for more complicated source configurations. Another method achieves uniform attenuation compensation by processing the Fourier transform of the sinogram [Bellini et al., 1979]. The method provides accurate compensation even for complicated source configurations.

A popular compensation method for uniform attenuation is that proposed by Chang [1978]. The method requires knowledge of the body contour. The information is used in calculating the average attenuation factor at each image point from all projection views. The array of attenuation factors is used to multiply the reconstructed image obtained without attenuation compensation. The result is the attenuation-compensated image. An iterative scheme also can be implemented for improved accuracy. In general, the Chang method performs well for uniform attenuation situations. However, the noise level in the reconstructed images increases with iteration number. Also, certain image features tend to fluctuate as a function of iteration. For these reasons, no more than one or two iterations are recommended.

Another class of methods for uniform attenuation compensation is based on analytical solution of the inverse of the attenuation Radon transform given in Equation 13.7 for a convex-shaped medium [Tretiak and Metz, 1980; Gullberg and Budinger, 1981]. The resultant compensation method involves multiplying the projection data by an exponential function. Then the FBP algorithm is used in the image reconstruction except that the ramp filter is modified such that its value is zero in the frequency range between 0 and  $\mu/2\pi$ , where  $\mu$  is the constant attenuation coefficient. The compensation method is easy to implement and provides good quantitative accuracy. However, it tends to amplify noise in the resulting image, and smoothing is required to obtain acceptable image quality [Gullberg and Budinger, 1981].

An analytical solution for the more complicated inverse attenuated Radon transform with nonuniform attenuation distribution (Equation 13.6) has been found difficult [Gullberg, 1979]. Instead, iterative approaches have been used to estimate a solution of the problem. The application is especially important in cardiac and lung SPECT studies. The iterative methods model the attenuation distribution in the projection and backprojection operations [Manglos et al., 1987; Tsui et al., 1989]. The ML criterion with the EM algorithm [Lange and Carson, 1984] has been used with success [Tsui et al., 1989]. The compensation method requires information about the attenuation distribution of the region to be imaged. Recently, transmission CT methods are being developed using existing SPECT systems to obtain attenuation distribution from the patient. The accurate attenuation compensation of cardiac SPECT promises to provide much improved quality and quantitative accuracy in cardiac SPECT images [Tsui et al., 1989, 1994a].

*Compensation for scatter:* As described earlier in this chapter, scattered photons carry misplaced positional information about the source distribution resulting in lower image contrast and inaccurate quantitation in SPECT images. Compensation for scatter will improve image contrast for better image quality and images that will more accurately represent the true object distribution. Much research has been devoted to develop scatter compensation methods that can be grouped into two general approaches. In the first approach, various methods have been developed to estimate the scatter contribution in the measured data. The scatter component is then subtracted from the measured data or from the reconstructed images to obtain scatter-free reconstructed images. The compensation method based on this approach tends to increase noise level in the compensated images.

One method estimates the scatter contribution as a convolution of the measured projection data with an empirically derived function [Axelsson et al., 1984]. Another method models the scatter component as the convolution of the primary (or unscattered) component of the projection data with an exponential function [Floyd et al., 1985]. The convolution method is extended to 3D by estimating the 2D scatter component [Yanch et al., 1988]. These convolution methods assume that the scatter response function is stationary, which is only an approximation.

The scatter component also has been estimated using two energy windows acquisition methods. One method estimates the scatter component in the primary energy window from the measured data obtained from a lower and adjacent energy window [Jaszczak et al., 1984, 1985b]. In a dual photopeak window (DPW) method, two nonoverlapping windows spanning the primary photopeak window are used [King et al., 1992]. This method provides more accurate estimation of the scatter response function.

Multiple energy windows also have been used to estimate the scatter component. One method uses two satellite energy windows that are placed directly above and below the photopeak window to estimate the scatter component in the center window [Ogawa et al., 1991]. In another method, the energy spectrum detected at each image pixel is used to predict the scatter contribution [Koral et al., 1988]. An energy-weighted acquisition (EWA) technique acquires data from multiple energy windows. The images reconstructed from these data are weighted with energy-dependent factors to minimize scatter contribution to the weighted image [DeVito et al., 1989; DeVito and Hamill, 1991]. Finally, the holospectral imaging method [Gagnon et al., 1989] estimates the scatter contribution from a series of eigenimages derived from images reconstructed from data obtained from a series of multiple energy windows.

In the second approach, the scatter photons are utilized in estimating the true object distribution. Without subtracting the scatter component, the compensated images are less noisy than those obtained from the first approach. In one method, an average scatter response function can be combined with the geometric response of the collimator–detector to form the total response of the imaging system [Gilland et al., 1988; Tsui et al., 1994a]. The total response function is then used to generate a restoration filter for an approximate geometric and scatter response compensation (see later).

Another class of methods, characterizes the exact scatter response function and incorporates it into iterative reconstruction algorithms for accurate compensation for scatter [Floyd et al., 1985; Frey and Tsui, 1992]. Since the exact scatter response functions are nonstationary and are asymmetric in shape, implementation of the methods requires extensive computations. However, efforts are being made to parameterize the scatter response function and to optimize the algorithm for substantial reduction in processing time [Frey and Tsui, 1991; Frey et al., 1993].

*Compensation for collimator–detector response:* As described earlier, for a typical collimator–detector, the response function broadens as the distance from the collimator face increases. The effect of the collimator–detector response is loss of spatial resolution and blurring of fine detail in SPECT images. Also, the spatially variant detector response function will cause nonisotropic point response in SPECT images [Knesaurek et al., 1989; Maniawski et al., 1991]. The spatially variant collimator–detector response is a major difficulty in its exact compensation.

By assuming an average and stationary collimator–detector response function, restoration filters can be used to provide partial and approximate compensation for the effects of the collimator–detector. Examples are the Metz [King et al., 1984, 1986] and Wiener [Penney et al., 1990] filters, where the inverse

of the average collimator–detector response function is used in the design of the restoration filters. Two-dimensional compensation is achieved by applying the 1D restoration filters to the 1D projection data, and 3D compensation by applying the 2D filters to the 2D projection images [Tsui et al., 1994b].

Analytical methods have been developed for compensation of the spatially variant detector response. A spatially variant filtering method has been proposed which is based on the frequency distance principle (FDP) [Edholm et al., 1986; Lewitt et al., 1989]. The method has been shown to provide an isotropic point response function in phantom SPECT images [Glick et al., 1993].

Iterative reconstruction methods also have been used to accurately compensate for both nonuniform attenuation and collimator–detector response by modeling the attenuation distribution and spatially variant detector response function in the projection and backprojection steps. The compensation methods have been applied in 2D reconstruction [Tsui et al., 1988; Formiconi et al., 1990], and more recently in 3D reconstruction [Zeng et al., 1991; Tsui et al., 1994b]. It has been found that the iterative reconstruction methods provide better image quality and more accurate quantitation when compared with the conventional restoration filtering techniques. Furthermore, 3D compensation outperforms 2D compensation at the expense of more extensive computations [Tsui et al., 1994b].

### 13.2.4 Sample SPECT Images

This section presents sample SPECT images to demonstrate the performance of various reconstruction and compensation methods. Two data sets were used. The first set was acquired from a 3D physical phantom that mimics a human brain perfusion study. The phantom study provided knowledge of the true radioactivity distribution for evaluation purposes. The second data set was obtained from a patient myocardial SPECT study using thallium-201.

Figure 13.12a shows the radioactivity distribution from a selected slice of a 3D brain phantom manufactured by the Data Spectrum Corporation. The phantom design was based on PET images from a normal patient to simulate cerebral blood flow [Hoffman et al., 1990]. The phantom was filled with water containing 74 mBq of Tc-99m. A single-camera-based GE 400AC/T SPECT system fitted with a high-resolution collimator was used for data collection. The projection data were acquired into  $128 \times 128$  matrices at 128 views over 360 degrees. Figure 13.12b shows the reconstructed image obtained from the FBP algorithm without any compensation. The poor image quality is due to statistical noise fluctuations, effects of attenuation (especially at the central portion of the image), loss of spatial resolution due to the collimator–detector response, and loss of contrast due to scatter.

Figure 13.12c shows the reconstructed image obtained with the application of a noise-smoothing filter and compensation for the uniform attenuation and scatter. The resulting image has lower noise level, reduced attenuation effect, and higher contrast as compared with the image shown in Figure 13.12b. Figure 13.12d is similar to Figure 13.12c except for an additional application of a Metz filter to partially compensate for the collimator–detector blurring. Figure 13.12e shows the reconstructed image obtained from the iterative ML-EM algorithm that accurately modeled the attenuation and spatially variant detector response. The much superior image quality is apparent.

Figure 13.13a shows a selected FBP reconstructed transaxial image slice from a typical patient myocardial SPECT study using thallium-201. Figure 13.13b shows the reconstructed image obtained from the Chang algorithm for approximate nonuniform attenuation compensation and 2D processing using a Metz filter for approximate compensation for collimator–detector response. Figure 13.13c shows the reconstructed image obtained from the iterative ML-EM algorithm using a measured transmission CT image for accurate attenuation compensation and a 2D model of the collimator–detector response for accurate collimator–detector response compensation. The reconstructed image in Figure 13.13d is similar to that in Figure 13.13b except that the Metz filter was implemented in 3D. Finally, the reconstructed image in Figure 13.13e is similar to that in Figure 13.13c except that a 3D model of the collimator–detector response is used. The superior image quality obtained from using an accurate 3D model of the imaging process is evident.

**FIGURE 13.12** Sample images from a phantom SPECT study. (a) Radioactivity distribution from a selected slice of a 3D brain phantom. (b) Reconstructed image obtained from the FBP algorithm without any compensation. (c) Reconstructed image obtained with the application of noise-smoothing filter and compensation for uniform attenuation and scatter. (d) Similar to (c) except for an additional application of a Metz filter to partially compensate for the collimator–detector blurring. (e) Reconstructed image similar to that obtained from the iterative ML-EM algorithm that accurately models the attenuation and spatially variant detector response. ### 13.2.5 Discussion

The development of SPECT has been a combination of advances in radiopharmaceuticals, instrumentation, image processing and reconstruction methods, and clinical applications. Although substantial progress has been made during the last decade, there are many opportunities for contributions from biomedical engineering in the future.

The future SPECT instrumentation will consist of more detector area to fully surround the patient for high detection efficiency and multiple contiguous transaxial slice capability. Multicamera SPECT systems will continue to dominate the commercial market. The use of new radiation detector materials and detector systems with high spatial resolution will receive increased attention. Continued research is needed to investigate special converging-hole collimator design geometries, fully 3D reconstruction algorithms, and their clinical applications.

**FIGURE 13.13** Sample images from a patient myocardial SPECT study using TI-201. (a) A selected transaxial image slice from a typical patient myocardial SPECT study using TI-201. The reconstructed image was obtained with the FBP algorithm without any compensation. (b) Reconstructed image obtained from the Chang algorithm for approximate nonuniform attenuation compensation and 2D processing using a Metz filter for approximate compensation for collimator–detector response. (c) Reconstructed image obtained from the iterative ML-EM algorithm using a measured transmission CT image for accurate attenuation compensation and 2D model of the collimator–detector response for accurate collimator–detector response compensation. (d) Similar to (b) except that the Metz filter was implemented in 3D. (e) Similar to (c) except that a 3D model of the collimator–detector response is used.

To improve image quality and to achieve quantitatively accurate SPECT images will continue to be the goals of image processing and image reconstruction methods for SPECT. An important direction of research in analytical reconstruction methods will involve solving the inverse Radon transform, which includes the effects of attenuation, the spatially variant collimator–detector response function, and scatter. The development of iterative reconstruction methods will require more accurate models of the complex SPECT imaging process, faster and more stable iterative algorithms, and more powerful computers and special computational hardware.

These improvements in SPECT instrumentation and image reconstruction methods, combined with newly developed radiopharmaceuticals, will bring SPECT images with increasingly higher quality and more accurate quantitation to nuclear medicine clinics for improved diagnosis and patient care.

### 14.1 Transducers

---

*Richard L. Goldberg and Stephen W. Smith*

An ultrasound transducer generates acoustic waves by converting magnetic, thermal, and electrical energy into mechanical energy. The most efficient technique for medical ultrasound uses the piezoelectric effect, which was first demonstrated in 1880 by Jacques and Pierre Curie [Curie and Curie, 1880]. They applied a stress to a quartz crystal and detected an electrical potential across opposite faces of the material. The Curies also discovered the inverse piezoelectric effect by applying an electric field across the crystal to induce a mechanical deformation. In this manner, a piezoelectric transducer converts an oscillating electric signal into an acoustic wave, and vice versa.

Many significant advances in ultrasound imaging have resulted from innovation in transducer technology. One such instance was the development of linear-array transducers. Previously, ultrasound systems had made an image by manually moving the transducer across the region of interest. Even the faster scanners had required several seconds to generate an ultrasound image, and as a result, only static targets could be scanned. On the other hand, if the acoustic beam could be scanned rapidly, clinicians could visualize

moving targets such as a beating heart. In addition, real-time imaging would provide instantaneous feedback to the clinician of the transducer position and system settings.

To implement real-time imaging, researchers developed new types of transducers that rapidly steer the acoustic beam. Piston-shaped transducers were designed to wobble or rotate about a fixed axis to mechanically steer the beam through a sector-shaped region. Linear sequential arrays were designed to electronically focus the beam in a rectangular image region. Linear phased-array transducers were designed to electronically steer and focus the beam at high speed in a sector image format.

This section describes the application of piezoelectric ceramics to transducer arrays for medical ultrasound. Background is presented on transducer materials and beam steering with phased arrays. Array performance is described, and the design of an idealized array is presented.

### 14.1.1 Transducer Materials

Ferroelectric materials strongly exhibit the piezoelectric effect, and they are ideal materials for medical ultrasound. For many years, the ferroelectric ceramic lead–zirconate–titanate (PZT) has been the standard transducer material for medical ultrasound, in part because of its high electromechanical conversion efficiency and low intrinsic losses. The properties of PZT can be adjusted by modifying the ratio of zirconium to titanium and introducing small amounts of other substances, such as lanthanum [Berlincourt, 1971]. Table 14.1 shows the material properties of linear-array elements made from PZT-5H.

PZT has a high dielectric constant compared with many piezoelectric materials, resulting in favorable electrical characteristics. The ceramic is mechanically strong, and it can be machined to various shapes and sizes. PZT can operate at temperatures up to 100°C or higher, and it is stable over long periods of time.

The disadvantages of PZT include its high **acoustic impedance** ( $Z = 30$  MRayls) compared with body tissue ( $Z = 1.5$  MRayls) and the presence of **lateral modes** in array elements. One or more acoustic matching layers can largely compensate for the acoustic impedance mismatch. The effect of lateral modes can be diminished by choosing the appropriate element dimensions or by subdicing the elements.

Other piezoelectric materials are used for various applications. Composites are made from PZT interspersed in an epoxy matrix [Smith, 1992]. Lateral modes are reduced in a composite because of its inhomogeneous structure. By combining the PZT and epoxy in different ratios and spatial distributions, one can tailor the composite's properties for different applications. Polyvinylidene difluoride (PVDF) is a ferroelectric polymer that has been used effectively in high-frequency transducers [Sherar and Foster, 1989]. The copolymer of PVDF with trifluoroethylene has an improved electromechanical conversion efficiency. Relaxor ferroelectric materials, such as lead–magnesium–niobate (PMN), become piezoelectric when a large direct-current (dc) bias voltage is applied [Takeuchi et al., 1990]. They have a very large dielectric constant ( $\epsilon > 20,000\epsilon_0$ ), resulting in higher transducer capacitance and a lower electrical impedance.

### 14.1.2 Scanning with Array Transducers

Array transducers use the same principles as acoustic lenses to focus an acoustic beam. In both cases, variable delays are applied across the transducer aperture. With a sequential or phased array, however,

**TABLE 14.1** Material Properties of Linear-Array Elements  
Made of PZT-5H

Parameter	Symbol	Value	Units
Density	$\rho$	7500	kg/m <sup>3</sup>
Speed of sound	$c$	3970	m/sec
Acoustic impedance	$Z$	29.75	MRayls
Relative dielectric constant	$\epsilon/\epsilon_0$	1475	None
Electromechanical coupling coefficient	$k$	0.698	None
Mechanical loss tangent	$\tan \delta_m$	0.015	None
Electrical loss tangent	$\tan \delta_e$	0.02	None

the delays are electronically controlled and can be changed instantaneously to focus the beam in different regions. Linear arrays were first developed for radar, sonar, and radio astronomy [Allen, 1964; Bobber, 1970], and they were implemented in a medical ultrasound system by Somer in 1968 [Somer, 1968].

Linear-array transducers have increased versatility over piston transducers. Electronic scanning involves no moving parts, and the focal point can be changed dynamically to any location in the scanning plane. The system can generate a wide variety of scan formats, and it can process the received echoes for other applications, such as dynamic receive focusing [von Ramm and Thurstone, 1976], correction for phase aberrations [Flax and O'Donnell, 1988; Trahey et al., 1990], and synthetic aperture imaging [Nock and Trahey, 1992].

The disadvantages of linear arrays are due to the increased complexity and higher cost of the transducers and scanners. For high-quality ultrasound images, many identical array elements are required (currently 128 and rising). The array elements are typically less than a millimeter on one side, and each has a separate connection to its own transmitter and receiver electronics.

The widespread use of array transducers for many applications indicates that the advantages often outweigh the disadvantages. In addition, improvement in transducer fabrication techniques and integrated circuit technology have led to more advanced array transducers and scanners.

### 14.1.2.1 Focusing and Steering with Phased Arrays

This section describes how a phased-array transducer can focus and steer an acoustic beam along a specific direction. An ultrasound image is formed by repeating this process over 100 times to interrogate a two-(2D) or three-dimensional (3D) region of the medium.

Figure 14.1a illustrates a simple example of a six-element linear array focusing the transmitted beam. One can assume that each array element is a point source that radiates a spherically shaped wavefront into the medium. Since the top element is farthest from the focus in this example, it is excited first. The remaining elements are excited at the appropriate time intervals so that the acoustic signals from all

**FIGURE 14.1** Focusing and steering an acoustic beam using a phased array. A 6-element linear array is shown (a) in the transmit mode and (b) in the receive mode. Dynamic focusing in receive allows the scanner to track the range of returning echoes.

the elements reach the focal point at the same time. According to Huygens' principle, the net acoustic signal is the sum of the signals that have arrived from each source. At the focal point, the contributions from every element add in phase to produce a peak in the acoustic signal. Elsewhere, at least some of the contributions add out of phase, reducing the signal relative to the peak.

For receiving an ultrasound echo, the phased array works in reverse. Figure 14.1b shows an echo originating from focus 1. The echo is incident on each array element at a different time interval. The received signals are electronically delayed so that the delayed signals add in phase for an echo originating at the focal point. For echoes originating elsewhere, at least some of the delayed signals will add out of phase, reducing the receive signal relative to the peak at the focus.

In the receive mode, the focal point can be dynamically adjusted so that it coincides with the range of returning echoes. After transmission of an acoustic pulse, the initial echoes return from targets near the transducer. Therefore, the scanner focuses the phased array on these targets, located at focus 1 in Figure 14.1b. As echoes return from more distant targets, the scanner focuses at a greater depth (focus 2 in the figure). Focal zones are established with adequate depth of field so that the targets are always in focus in receive. This process is called dynamic receive focusing and was first implemented by von Ramm and Thurstone in 1976 [von Ramm and Thurstone, 1976].

### 14.1.2.2 Array-Element Configurations

An ultrasound image is formed by repeating the preceding process many times to scan a 2D or 3D region of tissue. For a 2D image, the scanning plane is the *azimuth dimension*; the *elevation dimension* is perpendicular to the azimuth scanning plane. The shape of the region scanned is determined by the array-element configuration, described in the paragraph below.

*Linear Sequential Arrays:* Sequential linear arrays have as many as 512 elements in current commercial scanners. A subaperture of up to 128 elements is selected to operate at a given time. As shown in Figure 14.2a, the scanning lines are directed perpendicular to the face of the transducer; the acoustic beam is focused but not steered. The advantage of this scheme is that the array elements have high sensitivity when the beam is directed straight ahead. The disadvantage is that the field of view is limited to the rectangular region directly in front of the transducer. Linear-array transducers have a large footprint to obtain an adequate field of view.

*Curvilinear Arrays:* Curvilinear or convex arrays have a different shape than sequential linear arrays, but they operate in the same manner. In both cases, the scan lines are directed perpendicular to the transducer face. A curvilinear array, however, scans a wider field of view because of its convex shape, as shown in Figure 14.2b.

*Linear Phased Arrays:* The more advanced linear phased arrays have 128 elements. All the elements are used to transmit and receive each line of data. As shown in Figure 14.2c, the scanner steers the ultrasound beam through a sector-shaped region in the azimuth plane. Phased arrays scan a region that is significantly wider than the footprint of the transducer, making them suitable for scanning through restricted acoustic windows. As a result, these transducers are ideal for cardiac imaging, where the transducer must scan through a small window to avoid the obstructions of the ribs (bone) and lungs (air).

*1.5D Arrays:* The so-called 1.5D array is similar to a 2D array in construction but a 1D array in operation. The 1.5D array contains elements along both the azimuth and **elevation dimensions**. Features such dynamic focusing and phase correction can be implemented in both dimensions to improve image quality. Since a 1.5D array contains a limited number of elements in elevation (e.g., 3 to 9 elements), steering is not possible in that direction. Figure 14.2d illustrates a B-scan made with a 1.5D phased array. Linear sequential scanning is also possible with 1.5D arrays.

*2D Phased Arrays:* A 2D phased-array has a large number of elements in both the azimuth and elevation dimensions. Therefore, 2D arrays can focus and steer the acoustic beam in both dimensions. Using parallel receive processing [Shattuck et al., 1984], a 2D array can scan a pyramidal region in real time to produce a volumetric image, as shown in Figure 14.2e [von Ramm and Smith, 1990].

**FIGURE 14.2** Array-element configurations and the region scanned by the acoustic beam. (a) A sequential linear array scans a rectangular region; (b) a curvilinear array scans a sector-shaped region; (c) a linear phased array scans a sector-shaped region; (d) a 1.5D array scans a sector-shaped region; and (e) a 2D array scans a pyramidal-shaped region.

### 14.1.3 Linear-Array Transducer Performance

Designing an ultrasound transducer array involves many compromises. Ideally, a transducer has high sensitivity or SNR, good spatial resolution, and no artifacts. The individual array elements should have wide **angular response** in the steering dimensions, low cross-coupling, and an electrical impedance matched to the transmitter.

Figure 14.3a illustrates the connections to the transducer assembly. The transmitter and receiver circuits are located in the ultrasound scanner and are connected to the array elements through 1 to 2 m of coaxial cable. **Electrical matching networks** can be added to tune out the capacitance of the coaxial cable and/or the transducer element and increase the signal-to-noise ratio (SNR).

**FIGURE 14.3** (a) The connections between the ultrasound scanner and the transducer assembly for two elements of an array. (b) A more detailed picture of the transducer assembly for six elements of an array. (c) Coordinate system and labeling used to describe an array transducer.

A more detailed picture of six-transducer elements is shown in Figure 14.3b. Electrical leads connect to the ground and signal electrodes of the piezoelectric material. Acoustically, the array elements are loaded on the front side by one or two **quarter-wave matching layers** and the tissue medium. The matching layers may be made from glass or epoxy. A backing material, such as epoxy, loads the back side of the array elements. The faceplate protects the transducer assembly and also may act as an acoustic lens. Faceplates are often made from silicone or polyurethane.

The following sections describe several important characteristics of an array transducer. Figure 14.3c shows a six-element array and its dimensions. The element thickness, width, and length are labeled as  $t$ ,  $a$ , and  $b$ , respectively. The interelement spacing is  $d$ , and the total aperture size is  $D$  in azimuth. The acoustic wavelength in the load medium, usually human tissue, is designated as  $\lambda$ , while the wavelength in the transducer material is  $\lambda_t$ .

Examples are given below for a 128-element linear array operating at 5 MHz. The array is made of PZT-5H with element dimensions of  $0.1 \times 5 \times 0.3 \text{ mm}^3$ . The interelement spacing is  $d = 0.15 \text{ mm}$  in azimuth, and the total aperture is  $D = 128 \times 0.15 \text{ mm} = 19.3 \text{ mm}$  (see Table 14.1 for the piezoelectric material characteristics). The elements have an epoxy backing of  $Z = 3.25 \text{ MRayls}$ . For simplicity, the example array does not contain a  $\lambda/4$  matching layer.

### 14.1.3.1 Axial Resolution

*Axial resolution* determines the ability to distinguish between targets aligned in the axial direction (the direction of acoustic propagation). In pulse-echo imaging, the echoes off of two targets separated by  $r/2$  have a path length difference of  $r$ . If the acoustic pulse length is  $r$ , then echoes off the two targets are just distinguishable. As a result, the **axial resolution** is often defined as one-half the pulse length [Christensen, 1988]. A transducer with a high resonant frequency and a broad bandwidth has a short acoustic pulse and good axial resolution.

### 14.1.3.2 Radiation Pattern

The radiation pattern of a transducer determines theinsonified region of tissue. For good **lateral resolution** and sensitivity, the acoustic energy should be concentrated in a small region. The radiation pattern for a narrow-band or continuous-wave (CW) transducer is described by the Rayleigh–Sommerfeld diffraction formula [Goodman, 1986]. For a pulse-echo imaging system, this diffraction formula is not exact due to the broadband acoustic waves used. Nevertheless, the Rayleigh–Sommerfeld formula is a reasonable first-order approximation to the actual radiation pattern.

The following analysis considers only the azimuth scanning dimension. Near the focal point or in the far field, the Fraunhofer approximation reduces the diffraction formula to a Fourier transform formula. For a circular or rectangular aperture, the far field is at a range of

$$z > \frac{D^2}{4\lambda} \tag{14.1}$$

Figure 14.3c shows the coordinate system used to label the array aperture and its radiation pattern. The array aperture is described by

$$\text{Array}(x_1) = \text{rect}\left(\frac{x_1}{a}\right) * \text{comb}\left(\frac{x_1}{d}\right) \cdot \text{rect}\left(\frac{x_1}{D}\right) \tag{14.2}$$

where the  $\text{rect}(x)$  function is a rectangular pulse of width  $x$ , and the  $\text{comb}(x)$  function is a delta function repeated at intervals of  $x$ . The diffraction pattern is evaluated in the  $x_0$  plane at a distance  $z$  from the transducer, and  $\theta_x$  is the angle of the point  $x_0$  from the normal axis. With the Fraunhofer approximation, the normalized diffraction pattern is given by

$$P_x(\theta_x) = \text{sinc}\left(\frac{a \sin \theta_x}{\lambda}\right) \cdot \text{comb}\left(\frac{d \sin \theta_x}{\lambda}\right) * \text{sinc}\left(\frac{D \sin \theta_x}{\lambda}\right) \tag{14.3}$$

**FIGURE 14.4** Radiation pattern of Equation 14.3 for a 16-element array with  $a = \lambda$ ,  $d = 2\lambda$ , and  $D = 32\lambda$ . The angular response, the first term of Equation 14.3, is also shown as a dashed line.

in azimuth, where the Fourier transform of Equation 14.2 has been evaluated at the spatial frequency

$$f_x = \frac{x_0}{\lambda z} = \frac{\sin \theta_x}{\lambda} \tag{14.4}$$

Figure 14.4 shows a graph of Equation 14.3 for a 16-element array with  $a = \lambda$ ,  $d = 2\lambda$ , and  $D = 32\lambda$ . In the graph, the significance of each term is easily distinguished. The first term determines the angular response weighting, the second term determines the location of **grating lobes** off-axis, and the third term determines the shape of the main lobe and the grating lobes. The significance of *lateral resolution*, angular response, and grating lobes is seen from the CW diffraction pattern.

Lateral resolution determines the ability to distinguish between targets in the azimuth and elevation dimensions. According to the Rayleigh criterion [Goodman, 1986], the lateral resolution can be defined by the first null in the main lobe, which is determined from the third term of Equation 14.3.

$$\theta_x = \sin^{-1} \frac{\lambda}{D} \tag{14.5}$$

in the **azimuth dimension**. A larger aperture results in a more narrow main lobe and better resolution.

A broad angular response is desired to maintain sensitivity while steering off-axis. The first term of Equation 14.3 determines the one-way angular response. The element is usually surrounded by a soft baffle, such as air, resulting in an additional cosine factor in the radiation pattern [Selfridge et al., 1980]. Assuming transmit/receive reciprocity, the pulse-echo angular response for a single element is

$$P_x(\theta_x) = \frac{\sin^2(\pi a/\lambda \cdot \sin \theta_x)}{(\pi a/\lambda \cdot \sin \theta_x)} \cdot \cos^2 \theta_x \tag{14.6}$$

in the azimuth dimension. As the aperture size becomes smaller, the element more closely resembles a point source, and the angular response becomes more broad. Another useful indicator is the  $-6$ -dB angular response, defined as the full-width at half-maximum of the angular response graph.

Grating lobes are produced at a location where the path length difference to adjacent array elements is a multiple of a wavelength (the main lobe is located where the path length difference is zero). The acoustic contributions from the elements constructively interfere, producing off-axis peaks. The term grating lobe was originally used to describe the optical peaks produced by a diffraction grating. In ultrasound, grating

**FIGURE 14.5** Radiation pattern of the example array element with  $a = 0.1$  mm,  $d = 0.15$  mm,  $D = 19.2$  mm, and  $\lambda = 0.3$  mm. The angular response of Equation 14.6 was substituted into Equation 14.3 for this graph.

lobes are undesirable because they represent acoustic energy steered away from the main lobe. From the comb function in Equation 14.3, the grating lobes are located at

$$\theta_x = \sin^{-1} \frac{i\lambda}{d} \quad i = 1, 2, 3, \dots \tag{14.7}$$

in azimuth.

If  $d$  is a wavelength, then grating lobes are centered at  $\pm 90$  degrees from the steering direction in that dimension. Grating lobes at such large angles are less significant because the array elements have poor angular response in those regions. If the main lobe is steered at a large angle, however, the grating lobes are brought toward the front of the array. In this case, the angular response weighting produces a relatively weak main lobe and a relatively strong grating lobe. To eliminate grating lobes at all steering angles, the interelement spacing is set to  $\lambda/2$  or less [Steinberg, 1967].

Figure 14.5 shows the theoretical radiation pattern of the 128-element example. For this graph, the angular response weighting of Equation 14.6 was substituted into Equation 14.3. The lateral resolution, as defined by Equation 14.7,  $\theta_x = 0.9$  degrees at the focal point. The  $-6$ -dB angular response is  $\pm 40$  degrees from Equation 14.6.

### 14.1.3.3 Electrical Impedance

The electric impedance of an element relative to the electrical loads has a significant impact on transducer signal-to-noise ratio (SNR). At frequencies away from resonance, the transducer has electrical characteristics of a capacitor. The construction of the transducer is a parallel-plate capacitor with clamped capacitance of

$$C_0 = \epsilon^s \frac{ab}{t} \tag{14.8}$$

where  $\epsilon^s$  is the clamped dielectric constant.

Near resonance, equivalent circuits help to explain the impedance behavior of a transducer. The simplified circuit of Figure 14.6a is valid for transducers operating at series resonance without losses and with low acoustic impedance loads [Kino, 1987]. The mechanical resistance  $R_m$  represents the acoustic

**FIGURE 14.6** Simplified equivalent circuits for a piezoelectric transducer (a) near-series resonance and (b) near-parallel resonance.

loads as seen from the electrical terminals:

$$R_m = \frac{\pi}{4k^2\omega C_0} \cdot \frac{Z_1 + Z_2}{Z_C} \tag{14.9}$$

where  $k$  is the electromechanical coupling coefficient of the piezoelectric material,  $Z_C$  is the acoustic impedance of the piezoelectric material,  $Z_1$  is the acoustic impedance of the transducer backing, and  $Z_2$  is the acoustic impedance of the load medium (body tissue). The power dissipated through  $R_m$  corresponds to the acoustic output power from the transducer.

The mechanical inductance  $L_m$  and mechanical capacitance  $C_m$  are analogous to the inductance and capacitance of a mass-spring system. At the series resonant frequency of

$$f_s = \frac{1}{2\pi\sqrt{L_m C_m}} \tag{14.10}$$

the impedances of these components add to zero, resulting in a local impedance minimum.

The equivalent circuit of Figure 14.6a can be redrawn in the form shown in Figure 14.6b. In this circuit,  $C_0$  is the same as before, but the mechanical impedances have values of  $L'_m$ ,  $C'_m$ , and  $R_a$ . The resistive component  $R_a$  is

$$R_a = \frac{4k^2}{\pi\omega C_0} \cdot \frac{Z_C}{Z_1 - Z_2} \tag{14.11}$$

The inductor and capacitor combine to form an open circuit at the parallel resonant frequency of

$$f_p = \frac{1}{2\pi\sqrt{L'_m C'_m}} \tag{14.12}$$

The parallel resonance, which is at a slightly higher frequency than the series resonance, is indicated by a local impedance maximum.

Figure 14.7 shows a simulated plot of magnitude and phase versus frequency for the example array element described at the beginning of this subsection. The series resonance frequency is immediately identified at 5.0 MHz with an impedance minimum of  $|Z| = 350 \Omega$ . Parallel resonance occurs at 6.7 MHz with an impedance maximum of  $|Z| = 4000 \Omega$ . Note the capacitive behavior (approximately  $-90$ -degree phase) at frequencies far from resonance.

FIGURE 14.7 Complex electrical impedance of the example array element. Series resonance is located at 5.0 MHz, and parallel resonance is located at 6.7 MHz.

### 14.1.4 Designing a Phased-Array Transducer

In this section the design of an idealized phased-array transducer is considered in terms of the performance characteristics described above. Criteria are described for selecting array dimensions, acoustic backing and matching layers, and electrical matching networks.

#### 14.1.4.1 Choosing Array Dimensions

The array element thickness is determined by the parallel resonant frequency. For  $\lambda/2$  resonance, the thickness is

$$t = \frac{\lambda_t}{2} = \frac{c_t}{2f_p} \tag{14.13}$$

where  $c_t$  is the longitudinal speed of sound in the transducer material.

There are three constraints for choosing the element width and length (1) a nearly square cross-section should be avoided so that lateral vibrations are not coupled to the thickness vibration; as a rule of thumb [Kino and DeSilets, 1979],

$$a/t \leq 0.6 \quad \text{or} \quad a/t \geq 10 \tag{14.14}$$

(2) a small width and length are also desirable for a wide angular response weighting function; and (3) an interelement spacing of  $\lambda/2$  or less is necessary to eliminate grating lobes.

Fortunately, these requirements are consistent for PZT array elements. For all forms of PZT,  $c_t > 2c$ , where  $c$  is the speed of sound in body tissue (an average of 1540 m/sec). At a given frequency, then  $\lambda_t > 2\lambda$ . Also, Equation 14.13 states that  $\lambda_t = 2t$  at a frequency of  $f_p$ . By combining these equations,  $t > \lambda$  for PZT array elements operating at a frequency of  $f_p$ . If  $d = \lambda/2$ , then  $a < \lambda/2$  because of the finite kerf width that separates the elements. Given this observation, then  $a < t/2$ . This is consistent with Equation 14.14 to reduce lateral modes.

An element having  $d = \lambda/2$  also has adequate angular response. For illustrative purposes, one can assume a zero kerf width so that  $a = \lambda/2$ . In this case, the  $-6$ -dB angular response is  $\theta_x = \pm 35$  degrees according to Equation 14.6.

The array dimensions determine the transducer's lateral resolution. In the azimuth dimension, if  $d = \lambda/2$ , then the transducer aperture is  $D = n\lambda/2$ , where  $n$  is the number of elements in a fully sampled

array. From Equation 14.5, the lateral resolution in azimuth is

$$\theta_x = \sin^{-1} \frac{2}{n} \tag{14.15}$$

Therefore, the lateral resolution is independent of frequency in a fully sampled array with  $d = \lambda/2$ . For this configuration, the lateral resolution is improved by increasing the number of elements.

**14.1.4.2 Acoustic Backing and Matching Layers**

The backing and matching layers affect the transducer bandwidth and sensitivity. While a lossy, matched backing improves bandwidth, it also dissipates acoustic energy that could otherwise be transmitted into the tissue medium. Therefore, a low-impedance acoustic backing is preferred because it reflects the acoustic pulses toward the front side of the transducer. In this case, adequate bandwidth is maintained by acoustically matching the transducer to the tissue medium using matching layers.

Matching layers are designed with a thickness of  $\lambda/4$  at the center frequency and an acoustic impedance between those of the transducer  $Z_T$  and the load medium  $Z_L$ . The ideal acoustic impedances can be determined from several different models [Hunt et al., 1983]. Using the KLM equivalent circuit model [Desilets et al., 1978], the ideal acoustic impedance is

$$Z_1 = \sqrt[3]{Z_T Z_L^2} \tag{14.16}$$

for a single matching layer. For matching PZT-5H array elements ( $Z_T = 30$  MRayls) to a water load ( $Z_L = 1.5$  MRayls), a matching layer of  $Z_1 = 4.1$  MRayls should be chosen. If two matching layers are used, they should have acoustic impedances of

$$Z_1 \sqrt[7]{Z_T^4 Z_L^3} \tag{14.17a}$$

$$Z_2 \sqrt[7]{Z_T Z_L^6} \tag{14.17b}$$

In this case,  $Z_1 = 8.3$  MRayls and  $Z_2 = 2.3$  MRayls for matching PZT-5H to a water load.

When constructing a transducer, a practical matching layer material is not always available, with the ideal acoustic impedance (Equation 14.16 or Equation 14.17). Adequate bandwidth is obtained by using materials that have an impedance close to the ideal value. With a single matching layer, for example, conductive epoxy can be used with  $Z = 5.1$  MRayls.

**FIGURE 14.8** A transducer of real impedance  $R_t$  being excited by a transmitter with source impedance  $R_0$  and source voltage  $V_{in}$ .

### 14.1.4.3 Electrical Impedance Matching

Signal-to-noise ratio and bandwidth are also improved when electrical impedance of an array element is matched to that of the transmit circuitry. Consider the simplified circuit in Figure 14.8 with a transmitter of impedance  $R_0$  and a transducer of real impedance  $R_t$ . The power output is proportional to the power dissipated in  $R_t$ , as expressed as

$$P_{out} = \frac{V_{out}^2}{R_t} \text{ where } V_{out} = \frac{R_t}{R_0 + R_t} V_{in} \quad (14.18)$$

The power available from the transmitter is

$$P_{in} = \frac{(V_{in}/2)^2}{R_0} \quad (14.19)$$

into a matched load. From the two previous equations, the power efficiency is

$$\frac{P_{out}}{P_{in}} = \frac{4R_0R_t}{(R_0 + R_t)^2} \quad (14.20)$$

For a fixed-source impedance, the maximum efficiency is obtained by taking the derivative of Equation 14.20 with respect to  $R_t$  and setting it to zero. Maximum efficiency occurs when the source impedance is matched to the transducer impedance,  $R_0 = R_t$ .

In practice, the transducer has a complex impedance of  $R_m$  in parallel with  $C_0$  (see Figure 14.6), which is excited by a transmitter with a real impedance of  $50 \Omega$ . The transducer has a maximum efficiency when the imaginary component is tuned out and the real component is  $50 \Omega$ . This can be accomplished with electrical matching networks.

The capacitance  $C_0$  is tuned out in the frequency range near  $\Omega_0$  using an inductor of

$$L_0 = \frac{1}{\omega_0^2 C_0} \quad (14.21)$$

for an inductor in shunt, or

$$L_1 \frac{1}{\omega_0^2 C_0 + 1/R_m^2 C_0} \quad (14.22)$$

for an inductor in series. The example array elements described in the preceding subsection have  $C_0 = 22 \text{ pF}$  and  $R_m = 340 \Omega$  at series resonance of  $5.0 \text{ MHz}$ . Therefore, tuning inductors of  $L_0 = 46 \text{ nH}$  or  $L_1 = 2.4 \text{ nH}$  should be used.

A shunt inductor also raises the impedance of the transducer, as seen from the scanner, while a series inductor lowers the terminal impedance [Hunt et al., 1983]. For more significant changes in terminal impedance, transformers are used.

A transformer of turns ratio  $1 : N$  multiplies the terminal impedance by  $1/N^2$ . In the transmit mode,  $N$  can be adjusted so that the terminal impedance matches the transmitter impedance. In the receive mode, the open-circuit sensitivity varies as  $1/N$  because of the step-down transformer. The lower terminal impedance of the array element, however, provides increased ability to drive an electrical load.

More complicated circuits can be used for better electrical matching across a wide bandwidth [Hunt et al., 1983]. These circuits can be either passive, as above, or active. Inductors also can be used in the scanner to tune out the capacitance of the coaxial cable that loads the transducer on receive.

Another alternative for electrical matching is to use multilayer piezoelectric ceramics [Goldberg and Smith, 1994]. Figure 14.9 shows an example of a single layer and a five-layer array element with the same overall dimensions of  $a$ ,  $b$ , and  $t$ . Since the layers are connected electrically in parallel, the clamped

**FIGURE 14.9** (a) Conventional single-layer ceramic; (b) five-layer ceramic of the same overall dimensions. The layers are electrically in parallel and acoustically in series. The arrows indicate the piezoelectric poling directions of each layer.

capacitance of a multilayer ceramic (MLC) element is

$$C_0 = N \cdot \epsilon^S \cdot \frac{ab}{t/N} = N^2 \cdot C_{\text{single}} \tag{14.23}$$

where  $C_{\text{single}}$  is the capacitance of the single-layer element (Equation 14.8). As a result, the MLC impedance is reduced by a factor of  $N^2$ . Acoustically, the layers of the MLC are in series so the  $\lambda/2$  resonant thickness is  $t$ , the stack thickness.

To a first order, an  $N$ -layer ceramic has identical performance compared with a 1: $N$  transformer, but the impedance is transformed within the ceramic. MLCs also can be fabricated in large quantities more easily than hand-wound transformers. While MLCs do not tune out the reactive impedance, they make it easier to tune a low capacitance array element. By lowering the terminal impedance of an array element, MLCs significantly improve transducer SNR.

### 14.1.5 Summary

The piezoelectric transducer is an important component in the ultrasound imaging system. The transducer often consists of a liner array that can electronically focus an acoustic beam. Depending on the configuration of array elements, the region scanned may be sector shaped or rectangular in two dimensions or pyramidal shaped in three dimensions.

The transducer performance large determines the resolution and the signal-to-noise ratio of the resulting ultrasound image. The design of an array involves many compromises in choosing operating frequency and array-element dimensions. Electrical matching networks and quarter-wave matching layers may be added to improve transducer performance.

Further improvements in transducer performance may result from several areas of research. Newer materials, such as composites, are gaining widespread use in medical ultrasound. In addition, 1.5D arrays or 2D arrays may be employed to control the acoustic beam in both azimuth and elevation. Problems in fabrication and electrical impedance matching must be overcome to implement these arrays in an ultrasound system.

### Defining Terms

**Acoustic impedance:** In an analogy to transmission line impedance, the acoustic impedance is the ratio of pressure to particle velocity in a medium; more commonly, it is defined as  $Z = \rho c$ , where  $\rho$  = density and  $c$  = speed of sound in a medium [the units are  $\text{kg}/(\text{m}^2 \text{ sec})$  or Rayls].

**Angular response:** The radiation pattern versus angle for a single element of an array.

- Axial resolution:** The ability to distinguish between targets aligned in the axial direction (the direction of acoustic propagation).
- Azimuth dimension:** The lateral dimension that is along the scanning plane for an array transducer.
- Electrical matching networks:** Active or passive networks designed to tune out reactive components of the transducer and match the transducer impedance to the source and receiver impedance.
- Elevation dimension:** The lateral dimension that is perpendicular to the scanning plane for an array transducer.
- Grating lobes:** Undesirable artifacts in the radiation pattern of a transducer; they are produced at a location where the path length difference to adjacent array elements is a multiple of a wavelength.
- Lateral modes:** Transducer vibrations that occur in the lateral dimensions when the transducer is excited in the thickness dimension.
- Lateral resolution:** The ability to distinguish between targets in the azimuth and elevation dimensions (perpendicular to the axial dimension).
- Quarter-wave matching layers:** One or more layers of material placed between the transducer and the load medium (water or human tissue); they effectively match the acoustic impedance of the transducer to the load medium to improve the transducer bandwidth and signal-to-noise ratio.

## Further Information

A good overview of linear array design and performance is contained in von O.T. Ramm and S.W. Smith [1983], Beam steering with linear arrays, *IEEE Trans. Biomed. Eng.* 30: 438. The same issue contains a more general article on transducer design and performance: J.W. Hunt, M. Ardit, and F.S. Foster [1983], Ultrasound transducers for pulse-echo medical imaging, *IEEE Trans. Biomed. Eng.* 30: 453.

The journal *IEEE Transactions on Ultrasonics, Ferroelectrics, and Frequency Control* frequently contains articles on medical ultrasound transducers. For subscription information, contact IEEE Service Center, 445 Hoes Lane, P.O. Box 1331, Piscataway, NJ 08855-1331, phone (800) 678-IEEE.

Another good source is the proceedings of the IEEE Ultrasonics Symposium, published each year. Also, the proceedings from *New Developments in Ultrasonics Transducers and Transducer Systems*, edited by F.L. Lizzi, was published by SPIE, Vol. 1733, in 1992.

## 14.2 Ultrasonic Imaging

*Jack G. Mottley*

It was recognized long ago that the tissues of the body are inhomogeneous and that signals sent into them, like pulses of high-frequency sound, are reflected and scattered by those tissues. **Scattering**, or redirection of some of an incident energy signal to other directions by small particles, is why we see the beam of a spotlight in fog or smoke. That part of the scattered energy that returns to the transmitter is called the **backscatter**.

Ultrasonic imaging of the soft tissues of the body really began in the early 1970s. At that time, the technologies began to become available to capture and display the echoes backscattered by structures within the body as images, at first as static **compound images** and later as real-time moving images. The development followed much the same sequence (and borrowed much of the terminology) as did radar and sonar, from initial crude single-line-of-sight displays (**A-mode**) to recording these side by side to build up recordings over time to show motion (**M-mode**), to finally sweeping the transducer either mechanically or electronically over many directions and building up two-dimensional views (**B-mode or 2D**).

Since this technology was intended for civilian use, applications had to wait for the development of inexpensive data handling, storage, and display technologies. A-mode was usually shown on oscilloscopes, M-modes were printed onto specially treated light-sensitive thermal paper, and B-mode was initially built up as a static image in analog scan converters and shown on television monitors. Now all modes are produced in real time in proprietary scan converters, shown on television monitors, and recorded either on commercially available videotape recorders (for organs or studies in which motion is a part of the diagnostic information) or as still frames on photographic film (for those cases in which organ dimensions and appearance are useful, but motion is not important).

Using commercial videotape reduces expenses and greatly simplifies the review of cases for quality control and training, since review stations can be set up in offices or conference rooms with commonly

**FIGURE 14.10** Schematic representation of the signal received from along a single line of sight in a tissue. The rectified voltage signals are displayed for A-mode.

available monitors and videocassette recorders, and tapes from any imaging system can be played back. Also, the tapes are immediately available and do not have to be chemically processed.

Since the earliest systems were mostly capable of showing motion, the first applications were in studying the heart, which must move to carry out its function. A-mode and M-mode displays (see Figures 14.10–14.12) were able to demonstrate the motion of valves, thickening of heart chamber walls, relationships between heart motion and pressure, and other parameters that enabled diagnoses of heart problems that had been difficult or impossible before. For some valvular diseases, the preferred display format for diagnosis is still the M-mode, on which the speed of valve motions can be measured and the relations of valve motions to the electrocardiogram (ECG) are easily seen.

Later, as 2D displays became available, ultrasound was applied more and more to imaging of the soft abdominal organs and in obstetrics (Figure 14.13). In this format, organ dimensions and structural relations are seen more easily, and since the images are now made in real time, motions of organs such as the heart are still well appreciated. These images are used in a wide variety of areas from obstetrics and gynecology to ophthalmology to measure the dimensions of organs or tissue masses and have been widely accepted as a safe and convenient imaging modality.

### 14.2.1 Fundamentals

Strictly speaking, ultrasound is simply any sound wave whose frequency is above the limit of human hearing, which is usually taken to be 20 kHz. In the context of imaging of the human body, since frequency and wavelength (and therefore resolution) are inversely related, the lowest frequency of sound commonly used is around 1 MHz, with a constant trend toward higher frequencies in order to obtain better resolution. Axial resolution is approximately one wavelength, and at 1 MHz, the wavelength is 1.5 mm in most soft tissues, so one must go to 1.5 MHz to achieve 1-mm resolution.

**Attenuation** of ultrasonic signals increases with frequency in soft tissues, and so a tradeoff must be made between the depth of penetration that must be achieved for a particular application and the highest frequency that can be used. Applications that require deep penetration (e.g., cardiology, abdominal, obstetrics) typically use frequencies in the 2- to 5-MHz range, while those applications which only require shallow penetration but high resolution (e.g., ophthalmology, peripheral vascular, testicular) use

**FIGURE 14.11** Example of M-mode imaging of a heart at two points during the cardiac cycle. (a) Upper panel shows heart during diastole (relaxation) with a line of sight through it and the corresponding A-line converted to an M-line. (b) The lower panel shows the same heart during systole (contraction) and the A- and M-lines. Note the thicker walls and smaller ventricular cross-section during systole.

frequencies up to around 20 MHz. Intra-arterial imaging systems, requiring submillimeter resolution, use even higher frequencies of 20 to 50 MHz, and laboratory applications of ultrasonic microscopy use frequencies up to 100 or even 200 MHz to examine structures within individual cells.

There are two basic equations used in ultrasonic imaging. One relates the (one-way) distance  $d$  of an object that caused an echo from the transducer to the (round-trip) time delay  $t$  and speed of sound in the medium  $c$ :

$$d = \frac{1}{2}tc \tag{14.24}$$

The speed of sound in soft body tissues lies in a fairly narrow range from 1450 to 1520 m/sec. For rough estimates of time of flight, one often uses 1500 m/sec, which can be converted to 1.5 mm/ $\mu$ sec, a more convenient set of units. This leads to delay times for the longest-range measurements (20 cm) of 270  $\mu$ sec.

**FIGURE 14.12** Completed M-mode display obtained by showing the M-lines of Figure 14.11 side by side. The motion of the heart walls and their thickening and thinning are well appreciated. Often the ECG or heart sounds are also shown in order to coordinate the motions of the heart with other physiologic markers.

**FIGURE 14.13** Schematic representation of a heart and how a 2D image is constructed by scanning the transducer.

To allow echoes and reverberations to die out, one needs to wait several of these periods before launching the next interrogating pulse, so pulse repetition frequencies of about a kilohertz are possible.

The other equation relates the received signal strength  $S(t)$  to the transmitted signal  $T(t)$ , the transducer's properties  $B(t)$ , the attenuation of the signal path to and from the scatterer  $A(t)$ , and the strength of the scatterer  $h(t)$ :

$$S(t) = T(t) \otimes B(t) \otimes A(t) \otimes \eta(t) \tag{14.25}$$

where  $\otimes$  denotes time-domain convolution. Using the property of Fourier transforms that a convolution in the time domain is a multiplication in the frequency domain, this is more often written in the frequency domain as

$$S(f) = T(f)B(f)A(f)\eta(f) \tag{14.26}$$

where each term is the Fourier transform of the corresponding term in the time-domain expression 14.25 and is written as a function of frequency  $f$ .

The goal of most imaging applications is to measure and produce an image based on the local values of the scattering strength, which requires some assumptions to be made concerning each of the other terms. The amplitude of the transmitted signal  $T(f)$  is a user-adjustable parameter that simply adds a scale factor to the image values, unless it increases the returned signal to the point of saturating the receiver amplifier. Increasing the transmit power increases the strength of return from distant or faint echoes simply by increasing the power that illuminates them, like using a more powerful flashlight lets you see farther at night. Some care must be taken to not turn the transmit power up too high, since very high power levels are capable of causing acoustic cavitation or local heating of tissues, both of which can cause cellular damage. Advances in both electronics and transducers make it possible to transmit more and more power. For this reason, new ultrasonic imaging systems are required to display an index value that indicates the transmitted power. If the index exceeds established thresholds, it is possible that damage may occur, and the examiner should limit the time of exposure.

Most imaging systems are fairly narrow band, so the transducer properties  $B(f)$  are constant and produce only a scale factor to the image values. On phased-array systems it is possible to change the depth of focus on both transmit and receive. This improves image quality and detection of lesions by matching the focusing characteristics of the transducer to best image the object in question, like focusing a pair of binoculars on a particular object.

As the ultrasonic energy travels along the path from transmitter to scatterer and back, attenuation causes the signal to decrease with distance. This builds up as a line integral from time 0 to time  $t$  as

$$A(f, t) = e^{-\int_0^t \alpha(f) c dt'}$$

An average value of attenuation can be corrected for electronically by increasing the gain of the imaging system as a function of time (variously called time gain compensation [TGC] or depth gain compensation [DGC]). In addition, some systems allow for lateral portions of the image region to have different attenuation by adding a lateral gain compensation in which the gain is increased to either side of the center region of the image.

Time gain compensation is usually set to give a uniform gray level to the scattering along the center of the image. Most operators develop a “usual” setting on each machine, and if it becomes necessary to change those settings to obtain acceptable images on a patient, then that indicates that the patient has a higher attenuation or that there is a problem with the electronics, transducer, or acoustic coupling.

## 14.2.2 Applications and Example Calculations

As an example of calculating the time of flight of an ultrasonic image, consider the following.

*Example 1.* A tissue has a speed of sound  $c = 1460$  m/sec, and a given feature is 10 cm deep within. Calculate the time it will take an ultrasonic signal to travel from the surface to the feature and back.

*Answer:*  $t = 2 \times (10 \text{ cm}) / (1460 \text{ m/sec}) = 137 \mu\text{sec}$ , where the factor of 2 is to account for the round trip the signal has to make (i.e., go in and back out).

*Example 2.* Typical soft tissues attenuate ultrasonic signals at a rate of 0.5 dB/cm/MHz. How much attenuation would be suffered by a 3-MHz signal going through 5 cm of tissue and returning?

*Answer:*  $a = 3 \text{ MHz} \times (0.5 \text{ dB/cm/MHz}) / (8.686 \text{ dB/neper}) = 0.173 \text{ neper/cm}$ ,  $A(3 \text{ MHz}, 5 \text{ cm}) = e^{(-0.173 \text{ neper/cm}) \times (5 \text{ cm}) \times 2} = 0.177$ .

## 14.2.3 Economics

Ultrasonic imaging has many economic advantages over other imaging modalities. The imaging systems are typically much less expensive than those used for other modalities and do not require special

preparations of facilities such as shielding for x-rays or uniformity of magnetic field for MRI. Most ultrasonic imaging systems can be rolled easily from one location to another, so one system can be shared among technicians or examining rooms or even taken to patients' rooms for critically ill patients.

There are minimal expendables used in ultrasonic examinations, mostly the coupling gel used to couple the transducer to the skin and videotape or film for recording. Transducers are reusable and amortized over many examinations. These low costs make ultrasonic imaging one of the least expensive modalities, far preferred over others when indicated. The low cost also means these systems can be a part of private practices and used only occasionally.

As an indication of the interest in ultrasonic imaging as an alternative to other modalities, in 1993, the *Wall Street Journal* reported that spending in the United States on MRI units was approximately \$520 million, on CT units \$800 million, and on ultrasonic imaging systems \$1000 million, and that sales of ultrasound systems was growing at 15% annually [1].

## Defining Terms

**A-mode:** The original display of ultrasound measurements, in which the amplitude of the returned echoes along a single line is displayed on an oscilloscope.

**Attenuation:** The reduction in signal amplitude that occurs per unit distance traveled. Some attenuation occurs in homogeneous media such as water due to viscous heating and other phenomena, but that is very small and is usually taken to be negligible over the 10- to 20-cm distances typical of imaging systems. In inhomogeneous media such as soft tissues, the attenuation is much higher and increases with frequency. The values reported for most soft tissues lie around 0.5 dB/cm/MHz.

**Backscatter:** That part of a scattered signal that goes back toward the transmitter of the energy.

**B-mode or 2D:** The current display mode of choice. This is produced by sweeping the transducer from side to side and displaying the strength of the returned echoes as bright spots in their geometrically correct direction and distance.

**Compound images:** Images built up by adding, or compounding, data obtained from a single transducer or multiple transducers swept through arcs. Often these transducers were not fixed to a single point of rotation but could be swept over a surface of the body like the abdomen in order to build up a picture of the underlying organs such as the liver. This required an elaborate position-sensing apparatus attached to the patient's bed or the scanner and that the organ in question be held very still throughout the scanning process, or else the image was blurred.

**M-mode:** Followed A-mode by recording the strength of the echoes as dark spots on moving light-sensitive paper. Objects that move, such as the heart, caused standard patterns of motion to be displayed, and a lot of diagnostic information such as valve closure rates, whether valves opened or closed completely, and wall thickness could be obtained from M-mode recordings.

**Real-time images:** Images currently made on ultrasound imaging systems by rapidly sweeping the transducer through an arc either mechanically or electronically. Typical images might have 120 scan lines in each image, each 20 cm long. Since each line has a time of flight of  $267 \mu\text{sec}$ , a single frame takes  $120 \times 267 \mu\text{sec} = 32 \text{ msec}$ . It is therefore possible to produce images at standard video frame rates (30 frames/sec, or 33.3 msec/frame).

**Reflection:** Occurs at interfaces between large regions (much larger than a wavelength) of media with differing acoustic properties such as density or compressibility. This is similar to the reflection of light at interfaces and can be either total, like a mirror, or partial, like a half-silvered mirror or the ghostlike reflection seen in a sheet of glass.

**Scattering:** Occurs when there are irregularities or inhomogeneities in the acoustic properties of a medium over distances comparable with or smaller than the wavelength of the sound. Scattering from objects much smaller than a wavelength typically increases with frequency (the blue-sky law in optics), while that from an object comparable to a wavelength is constant with frequency (why clouds appear white).

## Further Information

There are many textbooks that contain good introduction to ultrasonic imaging. *Physical Principles of Ultrasonic Diagnosis*, by P. N. Wells, is a classic, and there is a new edition of another classic, *Diagnostic Ultrasound: Principles, Instruments and Exercises*, 4th ed., by Frederick Kremkau. Books on medical imaging that contain introductions to ultrasonic imaging include *Medical Imaging Systems*, by Albert Macovski; *Principles of Medical Imaging*, by Kirk Shung, Michael Smith, and Benjamin Tsui; and *Foundations of Medical Imaging*, by Zang-Hee Cho, Joie P. Jones, and Manbir Singh.

The monthly journals *IEEE Transactions on Ultrasonics, Ferroelectrics, and Frequency Control* and *IEEE Transactions on Biomedical Engineering* often contain information and research reports on ultrasonic imaging. For subscription information, contact IEEE Service Center, 445 Hoes Lane, P.O. Box 1331, Piscataway, NJ 08855-1331, phone (800) 678-4333. Another journal that often contains articles on ultrasonic imaging is the *Journal of the Acoustical Society of America*. For subscription information, contact AIP Circulation and Fulfillment Division, 500 Sunnyside Blvd., Woodbury, NY 11797-2999, phone (800) 344-6908; e-mail: [elecprod@pinet.aip.org](mailto:elecprod@pinet.aip.org).

There are many journals that deal with medical ultrasonic imaging exclusively. These include *Ultrasonic Imaging*, the *Journal of Ultrasound in Medicine*, American Institute of Ultrasound of Medicine (AIUM), 14750 Sweitzer Lane, Suite 100, Laurel, MD 20707-5906, and the *Journal of Ultrasound in Medicine and Biology*, Elsevier Science, Inc., 660 White Plains Road, Tarrytown, NY 10591-5153, e-mail: [esuk.usa@elsevier.com](mailto:esuk.usa@elsevier.com).

There are also specialty journals for particular medical areas, e.g., the *Journal of the American Society of Echocardiography*, that are available through medical libraries and are indexed in Index Medicus, Current Contents, Science Citation Index, and other databases.

## 14.3 Blood Flow Measurement Using Ultrasound

---

### *K. Whittaker Ferrara*

In order to introduce the fundamental challenges of blood velocity estimation, a brief description of the unique operating environment produced by the ultrasonic system, intervening tissue, and the scattering of ultrasound by blood is provided. In providing an overview of the parameters that differentiate this problem from radar and sonar target estimation problems, an introduction to the fluid dynamics of the cardiovascular system is presented, and the requirements of specific clinical applications are summarized. An overview of blood flow estimation systems and their performance limitations is then presented. Next, an overview of the theory of moving target estimation, with its roots in radar and sonar signal processing, is provided. The application of this theory to blood velocity estimation is then reviewed, and a number of signal processing strategies that have been applied to this problem are considered. Areas of new research including three-dimensional (3D) velocity estimation and the use of ultrasonic contrast agents are described in the final section.

### 14.3.1 Fundamental Concepts

In blood velocity estimation, the goal is not simply to estimate the mean target position and mean target velocity. The goal instead is to measure the velocity profile over the smallest region possible and to repeat this measurement quickly and accurately over the entire target. Therefore, the joint optimization of spatial, velocity, and temporal resolution is critical. In addition to the mean velocity, diagnostically useful information is contained in the volume of blood flowing through various vessels, spatial variations in the

velocity profile, and the presence of turbulence. While current methods have proven extremely valuable in the assessment of the velocity profile over an entire vessel, improved *spatial resolution* is required in several diagnostic situations. Improved *velocity resolution* is also desirable for a number of clinical applications. Blood velocity estimation algorithms implemented in current systems also suffer from a velocity ambiguity due to aliasing.

**14.3.1.1 Unique Features of the Operating Environment**

A number of features make blood flow estimation distinct from typical radar and sonar target estimation situations. The combination of factors associated with the beam formation system, properties of the intervening medium, and properties of the target medium lead to a difficult and unique operating environment. Figure 14.14 summarizes the operating environment of an ultrasonic blood velocity estimation system, and Table 14.2 summarizes the key parameters.

**14.3.1.1.1 Beam formation — data acquisition system**

The transducer bandwidth is limited. Most current transducers are limited to a 50 to 75% fractional bandwidth due to their finite dimensions and a variety of electrical and mechanical properties. This

FIGURE 14.14 Operating environment for the estimation of blood velocity.

TABLE 14.2 Important Parameters

Typical transducer center frequency	2–10 MHz
Maximum transducer fractional bandwidth	50–75%
Speed of sound $c$	1500–1600 m/sec
Acoustic wavelength ( $c = 1540$ )	0.154–1.54 mm
Phased-array size	$> 32 \cdot \text{wavelength}$
Sample volume size	$\text{mm}^3$
Blood velocity	Normal; up to 1 m/sec Pathological: up to 8 m/sec
Vessel wall echo/blood echo	20–40 dB
Diameter of a red blood cell	8.5 $\mu\text{m}$
Thickness of a red blood cell	2.4 $\mu\text{m}$
Volume of a red blood cell	$87 \pm 6 \text{ mm}^3$
Volume concentration of cells (hematocrit)	45%
Maximum concentration without cell deformation	58%

limits the form of the transmitted signal. The transmitted pulse is typically a short pulse with a **carrier frequency**, which is the center frequency in the spectrum of the transmitted signal.

Federal agencies monitor four distinct intensity levels. The levels are TASA, TASP, TPSA, and TPSP, where *T* represents temporal, *S* represents spatial, *A* represents average, and *P* represents peak. Therefore, the use of long bursts requires a proportionate reduction in the transmitted peak power. This may limit the signal-to-noise ratio (SNR) obtained with a long transmitted burst due to the weak reflections from the complex set of targets within the body.

#### 14.3.1.1.2 *Intervening medium*

Acoustic windows, which are locations for placement of a transducer to successfully interrogate particular organs, are limited in number and size. Due to the presence of bone and air, the number of usable acoustic windows is extremely limited. The reflection of acoustic energy from bone is only 3 dB below that of a perfect reflector [Wells, 1977]. Therefore, transducers cannot typically surround a desired imaging site. In many cases, it is difficult to find a single small access window. This limits the use of inverse techniques.

Intervening tissue produces acoustic refraction and reflection. Energy is reflected at unpredictable angles.

The **clutter**-to-signal ratio is very high. Clutter is the returned signal from stationary or slowly moving tissue, which can be 40 dB above the returned signal from blood. Movement of the vessel walls and valves during the cardiac cycle introduces a high-amplitude, low-frequency signal. This is typically considered to be unwanted noise, and a high-pass filter is used to eliminate the estimated wall frequencies.

The sampling rate is restricted. The speed of sound in tissue is low ( $\sim 1540$  m/sec), and each transmitted pulse must reach the target and return before the returned signal is recorded. Thus the sampling rate is restricted, and the aliasing limit is often exceeded.

The total observation time is limited (due to low acoustic velocity). In order to estimate the velocity of blood in all locations in a 2D field in real time, the estimate for each region must be based on the return from a limited number of pulses because of the low speed of sound.

Frequency-dependent attenuation affects the signal. Tissue acts as a low-pass transmission filter; the scattering functions as a high-pass filter. The received signal is therefore a distorted version of the transmitted signal. In order to estimate the effective filter function, the type and extent of each tissue type encountered by the wave must be known. Also, extension of the bandwidth of the transmitted signal to higher frequencies increases absorption, requiring higher power levels that can increase health concerns.

#### 14.3.1.1.3 *Target scattering medium (red blood cells)*

Multiple groups of scatterers are present. The target medium consists of multiple volumes of diffuse moving scatterers with velocity vectors that vary in magnitude and direction. The target medium is spread in space and velocity. The goal is to estimate the velocity over the smallest region possible.

There is a limited period of statistical stationarity. The underlying cardiac process can only be considered to be stationary for a limited time. This time was estimated to be 10 msec for the arterial system by Hatle and Angelsen [1985]. If an observation interval greater than this period is used, the average scatterer velocity cannot be considered to be constant.

### 14.3.1.2 **Overview of Ultrasonic Flow Estimation Systems**

Current ultrasonic imaging systems operate in a pulse-echo (PE) or continuous-wave (CW) intensity mapping mode. In pulse-echo mode, a very short pulse is transmitted, and the reflected signal is analyzed. For a continuous-wave system, a lower-intensity signal is continuously transmitted into the body, and the reflected energy is analyzed. In both types of systems, an acoustic wave is launched along a specific path into the body, and the return from this wave is processed as a function of time. The return is due to reflected waves from structures along the line of sight, combined with unwanted noise. Spatial selectivity is provided by beam formation performed on burst transmission and reception. Steering of the beam to a particular angle and creating a narrow beam width at the depth of interest are accomplished by an effective lens applied to the ultrasonic transducer. This lens may be produced by a contoured material, or it may be simulated by phased pulses applied to a transducer array. The spatial weighting pattern will

ultimately be the product of the effective lens on transmission and reception. The returned signal from the formed beam can be used to map the backscattered intensity into a two-dimensional gray-scale image, or to estimate target velocity. *We shall focus on the use of this information to estimate the velocity of red blood cells moving through the body.*

**14.3.1.2.1 Single sample volume doppler instruments**

One type of system uses the Doppler effect to estimate velocity in a single volume of blood, known as the sample volume, which is designated by the system operator. The Doppler shift frequency from a moving target can be shown to equal  $2f_c v/c$ , where  $f_c$  is the transducer center frequency in Hertz,  $c$  is the speed of sound within tissue, and  $v$  is the velocity component of the blood cells toward or away from the transducer. These “Doppler” systems transmit a train of long pulses with a well-defined carrier frequency and measure the Doppler shift in the returned signal. The spectrum of Doppler frequencies is proportional to the distribution of velocities present in the sample volume. The sample volume is on a cubic millimeter scale for typical pulse-echo systems operating in the frequency range of 2–10 MHz. Therefore, a thorough cardiac or peripheral vascular examination requires a long period. In these systems, 64–128 temporal samples are acquired for each estimate. The spectrum of these samples is typically computed using a fast Fourier transform (FFT) technique [Kay and Marple, 1981]. The range of velocities present within the sample volume can then be estimated. The spectrum is scaled to represent velocity and plotted on the vertical axis. Subsequent spectral estimates are then calculated and plotted vertically adjacent to the first estimate.

**14.3.1.2.2 Color flow mapping**

In color flow mapping, a pseudo-color velocity display is overlaid on a 2D gray-scale image. Simultaneous amplitude and velocity information is thus available for a 2D sector area of the body. The clinical advantage is a reduction in the examination time and the ability to visualize the velocity profile as a 2D map. Figure 14.15 shows a typical color flow map of ovarian blood flow combined with the Doppler spectrum of the region indicated by the small graphic sample volume. The color flow map shows color-encoded velocities superimposed on the gray-scale image with the velocity magnitude indicated by the color bar on the side of the image. Motion toward the transducer is shown in yellow and red, and motion away from the transducer is shown in blue and green, with the range of colors representing a range of velocities to a maximum of 6 cm/sec in each direction. Velocities above this limit would produce aliasing for the parameters used in optimizing the instrument for the display of ovarian flow. A velocity of 0 m/sec

**FIGURE 14.15** Flow map and Doppler spectrum for ovarian blood flow.

would be indicated by black, as shown at the center of the color bar. Early discussions of the implementation of color flow mapping systems can be found in Curry and White [1978] and Nowicki and Reid [1981].

The lower portion of the image presents an intensity-modulated display of instantaneous Doppler components along the vertical axis. As time progresses, the display is translated along the horizontal axis to generate a Doppler time history for the selected region of interest (provided by Acuson Corporation, Mountain View, California).

Limitations of color flow instruments result in part from the transmission of a narrowband (long) pulse that is needed for velocity estimation but degrades spatial resolution and prevents mapping of the spatial-velocity profile. Due to the velocity gradient in each blood vessel, the transmission of a long pulse also degrades the velocity resolution. This is caused by the simultaneous examination of blood cells moving at different velocities and the resulting mixing of regions of the scattering medium, which can be distinctly resolved on a conventional B-mode image. Since the limited speed of acoustic propagation velocity limits the sampling rate, a second problem is aliasing of the Doppler frequency. Third, information regarding the presence of velocity gradients and turbulence is desired and is not currently available. Finally, estimation of blood velocity based on the Doppler shift provides only an estimate of the axial velocity, which is the movement toward or away from the transducer, and cannot be used to estimate movement across the transducer beam. It is the 3D velocity magnitude that is of clinical interest.

For a color flow map, the velocity estimation technique is based on estimation of the mean Doppler shift using signal-processing techniques optimized for rapid (real-time) estimation of velocity in each region of the image. The transmitted pulse is typically a burst of 4 to 8 cycles of the carrier frequency. Data acquisition for use in velocity estimation is interleaved with the acquisition of information for the gray-scale image. Each frame of acquired data samples is used to generate one update of the image display. An azimuthal line is a line that describes the direction of the beam from the transducer to the target. A typical 2D ultrasound scanner uses 128 azimuthal lines per frame and 30 frames per second to generate a gray-scale image. Data acquisition for the velocity estimator used in color flow imaging requires an additional 4 to 18 transducer firings per azimuthal line and therefore reduces both the number of azimuthal lines and the number of frames per second. If the number of lines per frame is decreased, spatial undersampling or a reduced examination area results. If the number of frames per second is decreased, temporal undersampling results, and the display becomes difficult to interpret.

The number of data samples available for each color flow velocity estimate is reduced to 4–18 in comparison with the 64–128 data samples available to estimate velocity in a single sample volume Doppler mode. This reduction, required to estimate velocity over the 2D image, produces a large increase in the estimator variance.

### 14.3.1.3 Fluid Dynamics and the Cardiovascular System

In order to predict and adequately assess blood flow profiles within the body, the fluid dynamics of the cardiovascular system will be briefly reviewed. The idealized case known as Poiseuille flow will be considered first, allowed by a summary of the factors that disturb Poiseuille flow.

A Poiseuille flow model is appropriate in a long rigid circular pipe at a large distance from the entrance. The velocity in this case is described by the equation  $v/v_0 = 1 - (r/a)^2$ , where  $v$  represents the velocity parallel to the wall,  $v_0$  represents the center-line velocity,  $r$  is the radial distance variable, and  $a$  is the radius of the tube. In this case, the mean velocity is half the center-line velocity, and the volume flow rate is given by the mean velocity multiplied by the cross-sectional area of the vessel.

For the actual conditions within the arterial system, Poiseuille flow is only an approximation. The actual arterial geometry is tortuous and individualistic, and the resulting flow is perturbed by entrance effects and reflections. Reflections are produced by vascular branches and the geometric taper of the arterial diameter. In addition, spatial variations in vessel elasticity influence the amplitude and wave velocity of the arterial pulse. Several parameters can be used to characterize the velocity profile, including the Reynolds number, the Womersley number, the pulsatility index, and the resistive index. The pulsatility and resistive indices are frequently estimated during a clinical examination.

The Reynolds number is denoted  $Re$  and measures the ratio of fluid inertia to the viscous forces acting on the fluid. The Reynolds number is defined by  $Re = Dv'/\mu_k$ , where  $v'$  is the average cross-sectional velocity,  $\mu_k$  is the kinematic viscosity, and  $D$  is the vessel diameter. *Kinematic viscosity* is defined as the fluid viscosity divided by the fluid density. When the Reynolds number is high, fluid inertia dominates. This is true in the aorta and larger arteries, and bursts of turbulence are possible. When the number is low, viscous effects dominate.

The Womersly number is used to describe the effect introduced by the unsteady, pulsatile nature of the flow. This parameter, defined by  $a(\omega/\mu_k)^{1/2}$ , where  $\omega$  represents radian frequency of the wave, governs propagation along an elastic, fluid-filled tube. When the Womersly number is small, the instantaneous profile will be parabolic in shape, the flow is viscous dominated, and the profile is oscillatory and Poiseuille in nature. When the Womersly number is large, the flow will be blunt, inviscid, and have thin wall layers [Nicholas and O'Rourke, 1990].

The pulsatility index represents the ratio of the unsteady and steady velocity components of the flow. This shows the magnitude of the velocity changes that occur during acceleration and deceleration of blood constituents. Since the arterial pulse decreases in magnitude as it travels, this index is maximum in the aorta. The pulsatility index is given by the difference between the peak systolic and minimum diastolic values divided by the average value over one cardiac cycle. The Pourcelot, or resistance, index is the peak-to-peak swing in velocity from systole to diastole divided by the peak systolic value [Nichols and O'Rourke, 1990].

#### 14.3.1.3.1 Blood velocity profiles

Specific factors that influence the blood velocity profile include the entrance effect, vessel curvature, skewing, stenosis, acceleration, secondary flows, and turbulence. These effects are briefly introduced in this section.

The entrance effect is a result of fluid flow passing from a large tube or chamber into a smaller tube. The velocity distribution at the entrance becomes blunt. At a distance known as the entry length, the fully developed parabolic profile is restored, where the entry length is given by  $0.06Re \cdot (2a)$  [Nerem, 1985]. Distal to this point the profile is independent of distance.

If the vessel is curved, there will also be an entrance effect. The blunt profile in this case is skewed, with the peak velocity closer to the inner wall of curvature. When the fully developed profile occurs downstream, the distribution will again be skewed, with the maximal velocity toward the outer wall of curvature. Skewing also occurs at a bifurcation where proximal flow divides into daughter vessels. The higher-velocity components, which occurred at the center of the parent vessel, are then closer to the flow divider, and the velocity distribution in the daughter vessels is skewed toward the divider.

Stenosis, a localized narrowing of the vessel diameter, dampens the pulsatility of the flow and pressure waveforms. The downstream flow profile depends on the shape and degree of stenosis. Acceleration adds a flat component to the velocity profile. It is responsible for the flat profile during systole, as well as the negative flat component near the walls in the deceleration phase.

Secondary flows are swirling components which are superimposed on the main velocity profile. These occur at bends and branches, although regions of secondary flow can break away from the vessel wall and are then known as separated flow. These regions reattach to the wall at a point downstream.

One definition of turbulent flow is flow that demonstrates a random fluctuation in the magnitude and direction of velocity as a function of space and time. The intensity of turbulence is calculated using the magnitude of the fluctuating velocities. The relative intensity of turbulence is given by  $I_t = u_{rms}/u_{mean}$ , where  $u_{rms}$  represents the root-mean-square value of the fluctuating portion of the velocity, and  $u_{mean}$  represents the nonfluctuating mean velocity [Hinze, 1975].

#### 14.3.1.4 Clinical Applications and Their Requirements

Blood flow measurement with ultrasound is used in estimating the velocity and volume of flow within the heart and peripheral arteries and veins. Normal blood vessels vary in diameter up to a maximum of 2 cm,

although most vessels examined with ultrasound have a diameter of 1 to 10 mm. Motion of the vessel wall results in a diameter change of 5 to 10% during a cardiac cycle.

**14.3.1.4.1 Carotid arteries (common, internal, external)**

The evaluation of flow in the carotid arteries is of great clinical interest due to their importance in supplying blood to the brain, their proximity to the skin, and the wealth of experience that has been developed in characterizing vascular pathology through an evaluation of flow. The size of the carotid arteries is moderate; they narrow quickly from a maximum diameter of 0.8 cm. The shape of carotid flow waveforms over the cardiac cycle can be related to the pathophysiology of the circulation. Numerous attempts have been made to characterize the parameters of carotid waveforms and to compare these parameters in normal and stenotic cases. A number of indices have been used to summarize the information contained in these waveforms. The normal range of the Pourcelot index is 0.55 to 0.75. Many researchers have shown that accurate detection of a minor stenosis requires accurate quantitation of the entire Doppler spectrum and remains very difficult with current technology. The presence of a stenosis causes spectral broadening with the introduction of lower frequency or velocity components.

**14.3.1.4.2 Cardiology**

Blood velocity measurement in cardiology requires analysis of information at depths up to 18 cm. A relatively low center frequency (e.g., 2.5 to 3.5 MHz) typically is used in order to reduce attenuation. Areas commonly studied and the maximum rate of flow include the following [Hatle, 1985]:

Normal Adult Maximal Velocity (m/sec)	
Mitral flow	0.9
Tricuspid flow	0.5
Pulmonary artery	0.75
Left ventricle	0.9

**14.3.1.4.3 Aorta**

Aortic flow exhibits a blunt profile with entrance region characteristics. The entrance length is approximately 30 cm. The vessel diameter is approximately 2 cm. The mean Reynolds number is 2500 [Nerem, 1985], although the peak Reynolds number in the ascending aorta can range from 4300 to 8900, and the peak Reynolds number in the abdominal aorta is in the range of 400 to 1100 [Nichols and O'Rourke, 1990]. The maximal velocity is on the order of 1.35 m/sec. The flow is skewed in the aortic arch with a higher velocity at the inner wall. The flow is unsteady and laminar with possible turbulent bursts at peak systole.

**14.3.1.4.4 Peripheral arteries**

The peak systolic velocity [Hatsukami et al., 1992] in centimeters per second and standard deviation of the velocity measurement technique are provided below for selected arteries.

Artery	Peak systolic velocity (cm/sec)	Standard deviation
Proximal external iliac	99	22
Distal external iliac	96	13
Proximal common femoral	89	16
Distal common femoral	71	15
Proximal popliteal	53	9
Distal popliteal	53	24
Proximal peroneal	46	14
Distal peroneal	44	12

Nearly all the vessels above normally show some flow reversal during early diastole. A value of the pulsatility index of 5 or more in a limb artery is considered to be normal.

### 14.3.2 Velocity Estimation Techniques

Prior to the basic overview of theoretical approaches to target velocity estimation, it is necessary to understand a few basic features of the received signal from blood scatterers. It is the statistical correlation of the received signal in space and time that provides the opportunity to use a variety of velocity estimation strategies. Velocity estimation based on analysis of the frequency shift or the temporal correlation can be justified by these statistical properties.

Blood velocity mapping has unique features due to the substantial viscosity of blood and the spatial limitations imposed by the vessel walls. Because of these properties, groups of red blood cells can be tracked over a significant distance. Blood consists of a viscous incompressible fluid containing an average volume concentration of red blood cells of 45%, although this concentration varies randomly through the blood medium. The red blood cells are primarily responsible for producing the scattered wave, due to the difference in their acoustic properties in comparison with plasma. Recent research into the characteristics of blood has led to stochastic models for its properties as a function of time and space [Atkinson and Berry, 1974; Shung et al., 1976, 1992; Angelson, 1980; Mo and Cobbold, 1986]. The scattered signal from an insonified spatial volume is a random process that varies with the fluctuations in the density of scatterers in the insonified area, the shear rate within the vessel, and the hematocrit [Atkinson and Berry, 1974; Mo and Cobbold, 1986; Ferrara and Algazi, 1994a,b].

Since the concentration of cells varies randomly through the vessel, the magnitude of the returned signal varies when the group of scatterers being insonified changes. The returned amplitude from one spatial region is independent of the amplitude of the signal from adjacent spatial areas. As blood flows through a vessel, it transports cells whose backscattered signals can be tracked to estimate flow velocities.

Between the transmission of one pulse and the next, the scatterers move a small distance within the vessel. As shown in Figure 14.16, a group of cells with a particular concentration which are originally located at depth  $D_1$  at time  $T_1$  move to depth  $D_2$  at time  $T_2$ . The resulting change in axial depth produces a change in the delay of the signal returning to the transducer from each group of scatterers. This change in delay of the radiofrequency (RF) signal can be estimated in several ways. As shown in Figure 14.17, the returned signal from a set of sequential pulses then shows a random amplitude that can be used to estimate the velocity. Motion is detected using signal-processing techniques that estimate the shift of the signal between pulses.

FIGURE 14.16 Random concentration of red blood cells within a vessel at times  $T_1$  and  $T_2$ , where the change in depth from  $D_1$  to  $D_2$  would be used to estimate velocity.

**FIGURE 14.17** Received RF signal from three transmitted pulses, with a random amplitude which can be used to estimate the axial movement of blood between pulses. Motion is shown by the shift in the signal with a recognizable amplitude.

### 14.3.2.1 Clutter

In addition to the desired signal from the blood scatterers, the received signal contains clutter echoes returned from the surrounding tissue. An important component of this clutter signal arises from slowly moving vessel walls. The wall motion produces Doppler frequency shifts typically below 1 kHz, while the desired information from the blood cells exists in frequencies up to 15 kHz. Due to the smooth structure of the walls, energy is scattered coherently, and the clutter signal can be 40 dB above the scattered signal from blood. High-pass filters have been developed to remove the unwanted signal from the surrounding vessel walls.

### 14.3.2.2 Classic Theory of Velocity Estimation

Most current commercial ultrasound systems transmit a train of long pulses with a carrier frequency of 2 to 10 MHz and estimate velocity using the Doppler shift of the reflected signal. The transmission of a train of short pulses and new signal-processing strategies may improve the spatial resolution and quality of the resulting velocity estimate. In order to provide a basis for discussion and comparison of these techniques, the problem of blood velocity estimation is considered in this subsection from the view of classic velocity estimation theory typically applied to radar and sonar problems.

Important differences exist between classic detection and estimation for radar and sonar and the application of such techniques to medical ultrasound. The Van Trees [1971] approach is based on joint estimation of the Doppler shift and position over the entire target. In medical ultrasound, the velocity is estimated in small regions of a large target, where the target position is assumed to be known. While classic theories have been developed for estimation of all velocities within a large target by Van Trees and others, such techniques require a model for the velocity in each spatial region of interest. For the case of blood velocity estimation, the spatial variation in the velocity profile is complex, and it is difficult to postulate a model that can be used to derive a high-quality estimate. The theory of velocity estimation in the presence of spread targets is also discussed by Kennedy [1969] and Price [1968] as it applies to radar astronomy and dispersive communication channels.

It is the desire to improve the spatial and velocity resolution of the estimate of blood velocity that has motivated the evaluation of alternative wideband estimation techniques. Narrowband velocity estimation techniques use the Doppler frequency shift produced by the moving cells with a sample volume that is fixed in space. Wideband estimation techniques incorporate the change in delay of the returned pulse due to the motion of the moving cells. Within the classification of narrowband techniques are a number of estimation strategies to be detailed below. These include the fast Fourier transform (FFT), finite derivative estimation, the autocorrelator, and modern spectral estimation techniques, including autoregressive strategies. Within

FIGURE 14.18 Comparison of the axial distance traveled and the effective length of the transmitted pulse.

the classification of wideband techniques are cross-correlation strategies and the wideband **maximum likelihood** estimator (WMLE).

For improving the spatial mapping of blood velocity within the body, the transmission of short pulses is desirable. Therefore, it is of interest to assess the quality of velocity estimates made using narrowband and wideband estimators with transmitted signals of varying lengths. If  $(2\nu/c)BT \ll 1$ , where  $\nu$  represents the axial velocity of the target,  $c$  represents the speed of the wave in tissue,  $B$  represents the transmitted signal bandwidth, and  $T$  represents the total time interval used in estimating velocity within an individual region, then the change in delay produced by the motion of the red blood cells can be ignored [(Van Trees, 1971)].

This inequality is interpreted for the physical conditions of medical ultrasound in Figure 14.18. As shown in Figure 14.18, the value  $\nu T$  represents the axial distance traveled by the target while it is observed by the transducer beam, and  $c/(2B)$  represents the effective length of the signal that is used to observe the moving cells. If  $\nu T \ll c/(2B)$ , the shift in the position of a group of red blood cells during their travel through the ultrasonic beam is not a detectable fraction of the signal length. This leads to two important restrictions on estimation techniques. First, under the “narrowband” condition of transmission of a long (narrowband) pulse, motion of a group of cells through the beam can only be estimated using the Doppler frequency shift. Second, if the inequality is not satisfied and therefore the transmitted signal is short (wideband), faster-moving red blood cells leave the region of interest, and the use of a narrowband estimation technique produces a biased velocity estimate. Thus two strategies can be used to estimate velocity. A long (narrowband) pulse can be transmitted, and the signal from a fixed depth then can be used to estimate velocity. Alternatively, a short (wideband) signal can be transmitted in order to improve spatial resolution, and the estimator used to determine the velocity must move along with the red blood cells.

The inequality is now evaluated for typical parameters. When the angle between the axis of the beam and the axis of the vessel is 45 degrees, the axial distance traveled by the red blood cells while they cross the beam is equivalent to the lateral beam width. Using an axial distance  $\nu T$  of 0.75 mm, which is a reasonable lateral beam width, and an acoustic velocity of 1540 m/sec, the bandwidth of the transmitted pulse must be much less than 1.026 MHz for the narrowband approximation to be valid.

Due to practical advantages in the implementation of the smaller bandwidth required by **baseband signals**, the center frequency of the signal is often removed before velocity estimation. The processing required for the extraction of the baseband signal is shown in Figure 14.19. The returned signal from the transducer is amplified and coherently demodulated, through multiplication by the carrier frequency, and then a low-pass filter is applied to remove the signal sideband frequencies and noise. The remaining

signal is the **complex envelope**. A high-pass filter is then applied to the signal from each fixed depth to remove the unwanted echoes from stationary tissue. The output of this processing is denoted as  $I_k(t)$  for the in-phase signal from the  $k$ th pulse as a function of time and  $Q_k(t)$  for the quadrature signal from the  $k$ th pulse.

**14.3.2.3 Narrowband Estimation**

Narrowband estimation techniques that estimate velocity for blood at a fixed depth are described in this subsection. Both the classic Doppler technique, which frequently is used in single-sample volume systems, and the autocorrelator, which frequently is used in color flow mapping systems, are included, as well as a finite derivative estimator and an autoregressive estimator, which have been the subject of previous research. The autocorrelator is used in real-time color flow mapping systems due to the ease of implementation and the relatively small bias and variance.

**14.3.2.3.1 Classic Doppler Estimation**

If the carrier frequency is removed by coherently demodulating the signal, the change in delay of the RF signal becomes a change in the phase of the baseband signal. The Doppler shift frequency from a moving target equals  $2f_c v/c$ . With a center frequency of 5 MHz, sound velocity of 1540 m/sec, and blood velocity of 1 m/sec, the resulting frequency shift is 6493.5 Hz. For the estimation of blood velocity, the Doppler shift is not detectable using a single short pulse, and therefore, the signal from a fixed depth and a train of pulses is acquired.

A pulse-echo Doppler processing block diagram is shown in Figure 14.20. The baseband signal, from Figure 14.19, is shown as the input to this processing block. The received signal from each pulse is multiplied by a time window that is typically equal to the length of the transmitted pulse and integrated to produce a single data sample from each pulse. The set of data samples from a train of pulses is then Fourier-transformed, with the resulting frequency spectrum related to the axial velocity using the Doppler relationship.

Estimation of velocity using the Fourier transform of the signal from a fixed depth suffers from the limitations of all narrowband estimators, in that the variance of the estimate increases when a short pulse is transmitted. In addition, the velocity resolution produced using the Fourier transform is inversely

**FIGURE 14.19** Block diagram of the system architecture required to generate the baseband signal used by several estimation techniques.

**FIGURE 14.20** Block diagram of the system architecture required to estimate the Doppler spectrum from a set of baseband samples from a fixed depth.

proportional to the length of the data window. Therefore, if 64 pulses with a pulse repetition frequency of 5 kHz are used in the spectral estimate, the frequency resolution is on the order of 78.125 Hz (5000/64). The velocity resolution for a carrier frequency of 5 MHz and speed of sound of 1540 m/sec is then on the order of 1.2 cm/sec, determined from the Doppler relationship. Increasing the data window only improves the velocity resolution if the majority of the red blood cells have not left the sample volume and the flow conditions have not produced a decorrelation of the signal. It is this relationship between the data window and velocity resolution, a fundamental feature of Fourier transform techniques, that has motivated the use of autoregressive estimators. The frequency and velocity resolution are not fundamentally constrained by the data window using these modern spectral estimators introduced below.

**14.3.2.3.2 Autoregressive estimation (AR)**

In addition to the classic techniques discussed previously, higher-order modern spectral estimation techniques have been used in an attempt to improve the velocity resolution of the estimate. These techniques are again narrowband estimation techniques, since the data samples used in computing the estimate are obtained from a fixed depth. The challenges encountered in applying such techniques to blood velocity estimation include the selection of an appropriate order which adequately models the data sequence while providing the opportunity for real-time velocity estimation and determination of the length of the data sequence to be used in the estimation process.

The goal in autoregressive velocity estimation is to model the frequency content of the received signal by a set of coefficients which could be used to reconstruct the signal spectrum. The coefficients  $a(m)$  represent the AR parameters of the AR( $p$ ) process, where  $p$  is the number of poles in the model for the signal. Estimation of the AR parameters has been accomplished using the Burg and Levinson-Durbin recursion methods. The spectrum  $P(f)$  is then estimated using the following equation:

$$P(f) = k \left| 1 + \sum_{m=1}^p a(m) \exp[-i2\pi mf] \right|^{-2}$$

The poles of the AR transfer function which lie within the unit circle can then be determined based on these parameters, and the velocity associated with each pole is determined by the Doppler equation.

Both autoregressive and autoregressive moving-average estimation techniques have been applied to single-sample-volume Doppler estimation. Order selection for single-sample-volume AR estimators is discussed in Kaluzinski [1989]. Second-order autoregressive estimation has been applied to color flow mapping by Loupas and McDicken [1990] and Ahn and Park [1991]. Although two poles are not sufficient to model the data sequence, the parameters of a higher-order process cannot be estimated in real time. In addition, the estimation of parameters of a higher-order process using the limited number of data points available in color flow mapping produces a large variance. Loupas and McDicken have used the two poles to model the signal returned from blood. Ahn and Park have used one pole to model the received signal from blood and the second pole to model the stationary signal from the surrounding tissue.

While AR techniques are useful in modeling the stationary tissue and blood and in providing a high-resolution estimate of multiple velocity components, several problems have been encountered in the practical application to blood velocity estimation. First, the order required to adequately model any region of the vessel can change when stationary tissue is present in the sample volume or when the range of velocity components in the sample volume increases. In addition, the performance of an AR estimate degrades rapidly in the presence of white noise, particularly with a small number of data samples.

**14.3.2.3.3 Autocorrelator**

Kasai et al. [1985] and Barber et al. [1985] discussed a narrowband mean velocity estimation structure for use in color flow mapping. The phase of the signal correlation at a lag of one transmitted period is estimated and used in an inverse tangent calculation of the estimated mean Doppler shift  $f_{\text{mean}}$  of the returned signal. A block diagram of the autocorrelator is shown in Figure 14.21. The baseband signal is first integrated over a short depth window. The phase of the correlation at a lag of one pulse period is then

**FIGURE 14.21** Block diagram of the system architecture required to estimate the mean Doppler shift for each depth location using the autocorrelator.

estimated as the inverse tangent of the imaginary part of the correlation divided by the real part of the correlation. The estimated mean velocity  $v_{\text{mean}}$  of the scattering medium is then determined by scaling the estimated Doppler shift by several factors, including the expected center frequency of the returned signal.

The autocorrelator structure can be derived from the definition of instantaneous frequency, from the phase of the correlation at a lag of one period, or as the first-order autoregressive estimate of the mean frequency of a baseband signal. The contributions of uncorrelated noise should average to zero in both the numerator and denominator of the autocorrelator. This is an advantage because the autocorrelation estimate is unbiased when the input signal includes the desired flow signal and noise. Alternatively, in the absence of a moving target, the input to the autocorrelator may consist only of white noise. Under these conditions, both the numerator and denominator can average to values near zero, and the resulting output of the autocorrelator has a very large variance. This estimation structure must therefore be used with a power threshold that can determine the presence or absence of a signal from blood flow and set the output of the estimator to zero when this motion is absent.

The variance of the autocorrelation estimate increases with the transmitted bandwidth, and therefore, the performance is degraded by transmitting a short pulse.

**14.3.2.3.4 Finite derivative estimator (FDE)**

A second approach to mean velocity or frequency estimation is based on a finite implementation of a derivative operator. The finite derivative estimator is derived based on the first and second moments of the spectrum. The basis for this estimator comes from the definition of the spectral centroid:

$$v_{\text{mean}} = \frac{\int \omega S(\omega) d\omega}{\int S(\omega) d\omega} \tag{14.27}$$

The mean velocity is given by  $v_{\text{mean}}$ , which is a scaled version of the mean frequency, where the scaling constant is given by  $k'$  and  $S(\omega)$  represents the power spectral density. Letting  $R_r(\cdot)$  represent the complex signal correlation and  $t$  represent the difference between the two times used in the correlation estimate, Equation 14.27 is equivalent to

$$v_{\text{mean}} = k' \frac{[(\partial/\partial\tau)R_r(\tau)|_{\tau=0}]}{R_r(0)} \tag{14.28}$$

Writing the baseband signal as the sum  $I(t) + jQ(t)$  and letting  $E$  indicate the statistical expectation, Brody and Meindl ([974]) have shown that the mean velocity estimate can be rewritten as

$$v_{\text{mean}} = \frac{k' E\{(\partial/\partial t)[I(t)]Q(t) - (\partial/\partial t)[Q(t)]I(t)\}}{E[I^2(t) + Q^2(t)]} \tag{14.29}$$

The estimate of this quantity requires estimation of the derivative of the in-phase portion  $I(t)$  and quadrature portion  $Q(t)$  of the signal. For an analog, continuous-time implementation, the bias and

variance were evaluated by Brody and Meindl [1974]. The discrete case has been studied by Kristoffersen [1986]. The differentiation has been implemented in the discrete case as a finite difference or as a finite impulse response differentiation filter. The estimator is biased by noise, since the denominator represents power in the returned signal. Therefore, for nonzero noise power, the averaged noise power in the denominator will not be zero mean and will constitute a bias. The variance of the finite derivative estimator depends on the shape and bandwidth of the Doppler spectrum, as well as on the observation interval.

**14.3.2.4 Wideband Estimation Techniques**

It is desirable to transmit a short ultrasonic pulse in order to examine blood flow in small regions individually. For these short pulses, the narrowband approximation is not valid, and the estimation techniques used should track the motion of the red blood cells as they move to a new position over time. Estimation techniques that track the motion of the red blood cells are known as wideband estimation techniques and include cross-correlation techniques, the wideband maximum likelihood estimator and high time bandwidth estimation techniques. A thorough review of time-domain estimation techniques to estimate tissue motion is presented in Hein and O'Brien [1993].

**14.3.2.4.1 Cross-correlation estimator**

The use of time shift to estimate signal parameters has been studied extensively in radar. If the transmitted signal is known, a maximum likelihood (ML) solution for the estimation of delay has been discussed by Van Trees [1971] and others. If the signal shape is not known, the use of cross-correlation for delay estimation has been discussed by Helstrom [1968] and Knapp and Carter [1976]). If information regarding the statistics of the signal and noise are available, an MLE based on cross-correlation has been proposed by Knapp and Carter [1976] known as the generalized correlation method for the estimation of time delay.

Several researchers have applied cross-correlation analysis to medical ultrasound. Bonnefous and Pesque [1986], Embree and O'Brien [1986], Foster et al. [1990], and Trahey et al. [1987] have studied the estimation of mean velocity based on the change in delay due to target movement. This analysis has assumed the shape of the transmitted signal to be unknown, and a cross-correlation technique has been used to estimate the difference in delay between successive pulses. This differential delay has then been used to estimate target velocity, where the velocity estimate is now based on the change in delay of the signal over an axial window, by maximizing the cross-correlation of the returned signal over all possible target velocities. Cross-correlation processing is typically performed on the radiofrequency (RF) signal, and a typical cross-correlation block diagram is shown in Figure 14.22. A high-pass filter is first applied to the signal from a fixed depth to remove the unwanted return from stationary tissue. One advantage of this strategy is that the variance is now inversely proportional to bandwidth of the transmitted signal rather than proportional.

**14.3.2.4.2 Wideband Maximum Likelihood Estimator (WMLE)**

Wideband maximum likelihood estimation is a baseband strategy with performance properties that are similar to cross-correlation. The estimate of the velocity of the blood cells is jointly based on the shift in the signal envelope and the shift in the carrier frequency of the returned signal. This estimator can be derived using a model for the signal that is expected to be reflected from the moving blood medium after the signal passes through intervening tissue. The processing of the signal can be interpreted as a filter matched to

**FIGURE 14.22** Block diagram of the system architecture required to estimate the velocity at each depth using a cross-correlation estimator.

**FIGURE 14.23** Block diagram of the system architecture required to estimate the velocity at each depth using the wideband MLE.

the expected signal. A diagram of the processing required for the wideband maximum likelihood estimator is shown in Figure 14.23 [Ferrara and Algazi, 1991]. Assume that  $P$  pulses were transmitted. Required processing involves the delay of the signal from the  $(P - k)$ th pulse by an amount equal to  $2v/cT$ , which corresponds to the movement of the cells between pulses for a specific  $v$ , followed by multiplication by a frequency which corresponds to the expected Doppler shift frequency of the baseband returned signal. The result of this multiplication is summed for all pulses, and the maximum likelihood velocity is then the velocity which produces the largest output from this estimator structure.

**14.3.2.4.3 Estimation using high-time-bandwidth signals**

Several researchers have also investigated the use of long wideband signals including “chirp” modulated signals and pseudo-random noise for the estimation of blood velocity. These signals are transmitted continuously (or with a short “flyback” time). Since these signals require continual transmission, the instantaneous power level must be reduced in order to achieve safe average power levels.

Bertram [1979] concluded that transmission of a “chirp” appears to give inferior precision for range measurement and inferior resolution of closely spaced multiple targets than a conventional pulse-echo system applied to a similar transducer. Multiple targets confuse the analysis. Using a simple sawtooth waveform, it is not possible to differentiate a stationary target at one range from a moving target at a different range. This problem could possibly be overcome with increasing and decreasing frequency intervals. Axial resolution is independent of the modulation rate, dependent only on the spectral frequency range (which is limited).

The limitations of systems that have transmitted a long pulse of random noise and correlated the return with the transmitted signal include reverberations from outside the sample volume which degrade the signal-to-noise ratio (the federally required reduction in peak transmitted power also reduces SNR), limited signal bandwidth due to frequency-dependent attenuation in tissue, and the finite transducer bandwidth [Cooper and McGillem, 1972; Bendick and Newhouse, 1974].

**14.3.3 New Directions**

Areas of research interest, including estimation of the 3D velocity magnitude, volume flow estimation, the use of high-frequency catheter-based transducers, mapping blood flow within malignant tumors, a new display mode known as color Doppler energy, and the use of contrast agents, are summarized in this subsection.

*Estimation of the 3D velocity magnitude and beam vessel angle:* Continued research designed to provide an estimate of the 3D magnitude of the flow velocity includes the use of crossed-beam Doppler systems [Wang and Yao, 1982; Overbeck et al., 1992] and tracking of speckle in two and three dimensions [Trahey et al., 1987]. Mapping of the velocity estimate in two and three dimensions, resulting in a 3D color flow map has been described by Carson et al. [1992], Picot et al. [1993], and Cosgrove et al. [1990].

*Volume flow estimation:* Along with the peak velocity, instantaneous velocity profile, and velocity indices, a parameter of clinical interest is the volume of flow through vessels as a function of time. Estimation strategies for the determination of the volume of flow through a vessel have been

described by Embree and O'Brien [1990], Gill [1979], Hottinger and Meindl [1979], and Uematsu [1981].

*Intravascular ultrasound:* It has been shown that intravascular ultrasonic imaging can provide information about the composition of healthy tissue and atheroma as well as anatomic data. A number of researchers have now shown that using frequencies of 30 MHz or above, individual layers and tissue types can be differentiated [de Kroon et al., 1991a,b; Lockwood et al., 1991]. Although obvious changes in the vessel wall, such as dense fibrosis and calcification, have been identified with lower-frequency transducers, more subtle changes have been difficult to detect. Recent research has indicated that the character of plaque may be a more reliable predictor of subsequent cerebrovascular symptoms than the degree of vessel narrowing or the presence of ulceration [Merritt et al., 1992]. Therefore, the recognition of subtle differences in tissue type may be extremely valuable. One signal-processing challenge in imaging the vascular wall at frequencies of 30 MHz or above is the removal of the unwanted echo from red blood cells, which is a strong interfering signal at high frequencies.

*Vascular changes associated with tumors:* Three-dimensional color flow mapping of the vascular structure is proposed to provide new information for the differentiation of benign and malignant masses. Judah Folkman and associates first recognized the importance of tumor vascularity in 1971 [Folkman et al., 1971]. They hypothesized that the increased cell population required for the growth of a malignant tumor must be preceded by the production of new vessels. Subsequent work has shown that the walls of these vessels are deficient in muscular elements, and this deficiency results in a low impedance to flow [Gammill et al., 1976]. This change can be detected by an increase in diastolic flow and a change in the resistive index.

More recently, Less et al. [1991] have shown that the vascular architecture of solid mammary tumors has several distinct differences from normal tissues, at least in the microvasculature. A type of network exists that exhibits fluctuations in both the diameter and length of the vessel with increasing branch order. Current color flow mapping systems with a center frequency of 5 MHz or above have been able to detect abnormal flow with varying degrees of clinical sensitivity from 40 to 82% [Belcaro et al., 1988; Balu-Maestro et al., 1991; Luska et al., 1992]. Researchers using traditional Doppler systems have also reported a range of clinical sensitivity, with a general reporting of high sensitivity but moderate to low specificity. Burns et al., [1982] studied the signal from benign and malignant masses with 10-MHz CW Doppler. They hypothesized, and confirmed through angiography, that the tumors under study were fed by multiple small arteries, with a mean flow velocity below 10 cm/sec. Carson et al. [1992] compared 10-MHz CW Doppler to 5- and 7.5-MHz color flow mapping and concluded that while 3D reconstruction of the vasculature could provide significant additional information, color flow mapping systems must increase their ability to detect slow flow in small vessels in order to effectively map the vasculature.

*Ultrasound contrast agents:* The introduction of substances that enhance the ultrasonic echo signal from blood primarily through the production of microbubbles is of growing interest in ultrasonic flow measurement. The increased echo power may have a significant impact in contrast echocardiography, where acquisition of the signal from the coronary arteries has been difficult. In addition, such agents have been used to increase the backscattered signal from small vessels in masses that are suspected to be malignant. Contrast agents have been developed using sonicated albumen, saccharide microbubbles, and gelatin-encapsulated microbubbles.

Research to improve the sensitivity of flow measurement systems to low-velocity flow and small volumes of flow, with the goal of mapping the vasculature architecture, includes the use of ultrasonic contrast agents with conventional Doppler signal processing [Hartley et al., 1993], as well as the detection of the second harmonic of the transducer center frequency [Shrope and Newhouse, 1993].

*Color Doppler energy:* During 1993, a new format for the presentation of the returned signal from the blood scattering medium was introduced and termed color Doppler energy (CDE) or color power imaging (CPI). In this format, the backscattered signal is filtered to remove the signal from stationary tissue, and the remaining energy in the backscattered signal is color encoded and displayed as an overlay on the gray-scale image. The advantage of this signal-processing technique is the sensitivity to very low flow velocities.

## Defining Terms

**Baseband signal:** The received signal after the center frequency component (carrier frequency) has been removed by demodulation.

**Carrier frequency:** The center frequency in the spectrum of the transmitted signal.

**Clutter:** An unwanted fixed signal component generated by stationary targets typically outside the region of interest (such as vessel walls).

**Complex envelope:** A signal expressed by the product of the carrier, a high-frequency component, and other lower-frequency components that comprise the envelope. The envelope is usually expressed in complex form.

**Maximum likelihood:** A statistical estimation technique that maximizes the probability of the occurrence of an event to estimate a parameter. ML estimate is the minimum variance, unbiased estimate.

Visualization of internal structures of opaque biologic objects is essential in many biomedical studies. Limited by the penetration depth of the probing sources (photons and electrons) and the lack of endogenous contrast, conventional forms of microscopy such as optical microscopy and electron microscopy require tissues to be sectioned into thin slices and stained with organic chemicals or heavy-metal compounds prior to examination. These invasive and destructive procedures, as well as the harmful radiation in the case of electron microscopy, make it difficult to obtain three-dimensional information and virtually impossible to study biologic tissues *in vivo*.

Magnetic resonance (MR) microscopy is a new form of microscopy that overcomes the aforementioned limitations. Operating in the radiofrequency (RF) range, MR microscopy allows biologic samples to be examined in the living state without bleaching or damage by ionizing radiation and in fresh and fixed specimens after minimal preparation. It also can use a number of endogenous contrast mechanisms that are directly related to tissue biochemistry, physiology, and pathology. Additionally, MR microscopy is digital and three-dimensional; internal structures of opaque tissues can be quantitatively mapped out in three dimensions to accurately reveal their histopathologic status. These unique properties provide new opportunities for biomedical scientists to attack problems that have been difficult to investigate using conventional techniques.

Conceptually, MR microscopy is an extension of magnetic resonance imaging (MRI) to the microscopic domain, generating images with spatial resolution better than 100 nm [Lauterbur, 1984]. As such, MR microscopy is challenged by a new set of theoretical and technical problems [Johnson et al., 1992]. For example, to improve isotropic resolution from 1 to 10 nm, signal-to-noise ratio (SNR) per voxel must be increased by a million times to maintain the same image quality. In order to do so, almost every component of hardware must be optimized to the fullest extent, pulse sequences have to be carefully

designed to minimize any potential signal loss, and special software and dedicated computation facilities must be involved to handle large image arrays (e.g.,  $256^3$ ). Over the past decade, development of MR microscopy has focused mainly on these issues. Persistent efforts by many researchers have recently led to images with isotropic resolution of the order of  $\sim 10 \mu\text{m}$  [Cho et al., 1992; Jacobs and Fraser, 1994; Johnson et al., 1992; Zhou and Lauterbur, 1992]. The significant resolution improvement opens up a broad range of applications, from histology to cancer biology and from toxicology to plant biology [Johnson et al., 1992]. In this chapter we will first discuss the basic principles of MR microscopy, with special attention to such issues as resolution limits and sensitivity improvements. Then we will give an overview of the instrumentation. Finally, we will provide some examples to demonstrate the applications.

## 15.1 Basic Principles

### 15.1.1 Spatial Encoding and Decoding

Any digital imaging systems involve two processes. First, spatially resolved information must be encoded into a measurable signal, and second, the spatially encoded signal must be decoded to produce an image. In MR microscopy, the spatial encoding process is accomplished by acquiring nuclear magnetic resonance (NMR) signals under the influence of three orthogonal magnetic field gradients. There are many ways that a gradient can interact with a spin system. If the gradient is applied during a frequency-selective RF pulse, then the NMR signal arises only from a thin slab along the gradient direction. Thus a slice is selected from a three-dimensional (3D) object. If the gradient is applied during the acquisition of an NMR signal, the signal will consist of a range of spatially dependent frequencies given by

$$\omega(\vec{r}) = \gamma B_0 + \gamma \vec{G} \cdot \vec{r} \quad (15.1)$$

where  $\gamma$  is gyromagnetic ratio,  $B_0$  is the static magnetic field,  $\vec{G}$  is the magnetic field gradient, and  $\vec{r}$  is the spatial variable. In this way, the spatial information along  $\vec{G}$  direction is encoded into the signal as frequency variations. This method of encoding is called frequency encoding, and the gradient is referred to as a frequency-encoding gradient (or read-out gradient). If the gradient is applied for a fixed amount of time  $t_{pe}$  before the signal acquisition, then the phase of the signal, instead of the frequency, becomes spatially dependent, as given by

$$\phi(\vec{r}) = \int_0^{t_{pe}} \omega(\vec{r}) dt = \phi_0 + \int_0^{t_{pe}} \gamma \vec{G} \cdot \vec{r} dt \quad (15.2)$$

where  $\phi_0$  is the phase originated from the static magnetic field. This encoding method is known as phase encoding, and the gradient is called a phase-encoding gradient.

Based on the three basic spatial encoding approaches, many imaging schemes can be synthesized. For two-dimensional (2D) imaging, a slice-selection gradient is first applied to confine the NMR signal in a slice. Spatial encoding within the slice is then accomplished by frequency encoding and by phase encoding. For 3D imaging, the slice-selection gradient is replaced by either a frequency-encoding or a phase-encoding gradient. If all spatial directions are frequency-encoded, the encoding scheme is called projection acquisition, and the corresponding decoding method is called projection reconstruction [Lai and Lauterbur, 1981; Lauterbur, 1973]. If one of the spatial dimensions is frequency encoded while the rest are phase encoded, the method is known as Fourier imaging, and the image can be reconstructed simply by a multidimensional Fourier transform [Edelstein et al., 1980; Kumar et al., 1975]. Although other methods do exist, projection reconstruction and Fourier imaging are the two most popular in MR microscopy.

Projection reconstruction is particularly useful for spin systems with short apparent  $T_2$  values, such as protons in lung and liver. Since the  $T_2$  of most tissues decreases as static magnetic field increases, the advantage of projection reconstruction is more obvious at high magnetic fields. Another advantage of projection reconstruction is its superior SNR to Fourier imaging. This advantage has been theoretically

analyzed and experimentally demonstrated in a number of independent studies [Callaghan and Eccles, 1987; Gewalt et al., 1993; Zhou and Lauterbur, 1992]. Recently, it also has been shown that projection reconstruction is less sensitive to motion and motion artifacts can be effectively reduced using sinograms [Glover and Noll, 1993; Glover and Pauly, 1992; Gmitro and Alexander, 1993]. Unlike projection reconstruction, data acquisition in Fourier imaging generates Fourier coefficients of the image in a cartesian coordinate. Since multidimensional fast Fourier transform algorithms can be applied directly to the raw data, Fourier imaging is computationally more efficient than projection reconstruction. This advantage is most evident when reconstructing 3D images with large arrays (e.g., 2563). In addition, Fourier transform imaging is less prone to image artifacts arising from various off-resonance effects and is more robust in applications such as chemical shift imaging [Brown et al., 1982] and flow imaging [Moran, 1982].

### 15.1.2 Image Contrast

A variety of contrast mechanisms can be exploited in MR microscopy, including spin density ( $r$ ), spin-spin relaxation time ( $T_1$ ), spin-lattice relaxation time ( $T_2$ ), apparent  $T_2$  relaxation time ( $T_2^*$ ), diffusion coefficient ( $D$ ), flow and chemical shift ( $d$ ). One of the contrasts can be highlighted by varying data-acquisition parameters or by choosing different pulse sequences. Table 15.1 summarizes the pulse sequences and data-acquisition parameters to obtain each of the preceding contrasts.

In high-field MR microscopy ( $>1.5T$ ),  $T_2$  and diffusion contrast are strongly coupled together. An increasing number of evidences indicate that the apparent  $T_2$  contrast observed in high-field MR microscopy is largely due to microscopic magnetic susceptibility variations [Majumdar and Gore, 1988; Zhong and Gore, 1991]. The magnetic susceptibility difference produces strong local magnetic field gradients. Molecular diffusion through the induced gradients causes significant signal loss. In addition, the large external magnetic field gradients required for spatial encoding further increase the diffusion-induced signal loss. Since the signal loss has similar dependence on echo time (TE) to  $T_2$ -related loss, the diffusion contrast mechanism is involved in virtually all  $T_2$ -weighted images. This unique contrast mechanism provides a direct means to probe the microscopic tissue heterogeneities and forms the basis for many histopathologic studies [Benveniste et al., 1992; Zhou et al., 1994].

Chemical shift is another unique contrast mechanism. Changes in chemical shift can directly reveal tissue metabolic and histopathologic stages. This mechanism exists in many spin systems such as  $^1H$ ,  $^{31}P$ , and  $^{13}C$ . Recently, Lean et al. [1993] showed that based on proton chemical shifts, MR microscopy can detect tissue pathologic changes with superior sensitivity to optical microscopy in a number of tumor models. A major limitation for chemical-shift MR microscopy is the rather poor spatial resolution, since most spin species other than water protons are of considerably low concentration and sensitivity. In addition, the long data-acquisition time required to resolve both spatial and spectral information also appears as an obstacle.

**TABLE 15.1** Choice of Acquisition Parameters for Different Image Contrasts

Contrast	TR <sup>b</sup>	TE <sup>b</sup>	Pulse sequences <sup>a</sup>
$r$	3–5 $T_{1,max}$	$\ll T_{2,min}$	SE, GE
$T_1$	$-T_{1,avg}$	$\ll T_{2,min}$	SE, GE
$T_2$	3–5 $T_{1,max}$	$\sim T_{2,avg}$	SE, FSE
$T_2^*$	3–5 $T_{1,max}$	$\sim T_{s,avg}^*$	GE
$D^c$	3–5 $T_{1,max}$	$\ll T_{2,min}$	Diffusion-weighted SE, GE, or FSE

<sup>a</sup> SE: spin-echo; GE: gradient echo; FSE: fast spin echo.

<sup>b</sup> Subscripts min, max and avg stand for minimum, maximum and average values, respectively.

<sup>c</sup> A pair of diffusion weighting gradients must be used.

## 15.2 Resolution Limits

### 15.2.1 Intrinsic Resolution Limit

Intrinsic resolution is defined as the width of the point-spread function originated from physics laws. In MR microscopy, the intrinsic resolution arises from two sources: natural linewidth broadening and diffusion [Callaghan and Eccles, 1988; Cho et al., 1988; House, 1984].

In most conventional pulse sequences, natural linewidth broadening affects the resolution limit only in the frequency-encoding direction. In some special cases, such as fast spin echo [Hennig et al., 1986] and echo planar imaging [Mansfield and Maudsley, 1977], natural linewidth broadening also imposes resolution limits in the phase-encoding direction [Zhou et al., 1993]. The natural linewidth resolution limit, defined by

$$\Delta r_{\text{n.l.w.}} = \frac{2}{\gamma GT_2} \quad (15.3)$$

is determined by the  $T_2$  relaxation time and can be improved using a stronger gradient  $G$ . To obtain 1 mm resolution from a specimen with  $T_2 = 50$  msec, the gradient should be at least 14.9 G/cm. This gradient requirement is well within the range of most MR microscopes.

Molecular diffusion affects the spatial resolution in a number of ways. The bounded diffusion is responsible for many interesting phenomena known as edge enhancements [Callaghan et al., 1993; Hills et al., 1990; Hyslop and Lauterbur, 1991; Putz et al., 1991]. They are observable only at the microscopic resolution and are potentially useful to detect microscopic boundaries. The unbounded diffusion, on the other hand, causes signal attenuation, line broadening, and phase misregistration. All these effects originate from an incoherent and irreversible phase-dispersion. The root-mean-square value of the phase dispersion is

$$\sigma = \gamma \left\{ 2D \int_0^t \left[ \int_{t'}^t G(t'') dt'' \right]^2 dt' \right\}^{1/2} \quad (15.4)$$

where  $t'$  and  $t$  are pulse-sequence-dependent time variables defined by Ahn and Cho [1989]. Because of the phase uncertainty, an intrinsic resolution limit along the phase encoding direction arises:

$$\Delta r_{\text{pe}} = \frac{\sigma}{\gamma \int_0^t G_{\text{pe}}(t') dt'} \quad (15.5)$$

For a rectangularly shaped phase-encoding gradient, the preceding equation can be reduced to a very simple form:

$$\Delta r_{\text{pe}} = \sqrt{\frac{2}{3} D t_{\text{pe}}} \quad (15.6)$$

This simple result indicates that the diffusion resolution limit in the phase-encoded direction is determined only by the phase-encoding time  $t_{\text{pe}}$  ( $D$  is a constant for a chosen sample). This is so because the phase uncertainty is introduced only during the phase-encoding period. Once the spins are phase-encoded, they always carry the same spatial information no matter where they diffuse to. In the frequency-encoding direction, diffusion imposes resolution limits by broadening the point-spread function. Unlike natural linewidth broadening, broadening caused by diffusion is pulse-sequence-dependent. For the simplest pulse sequence, a 3D projection acquisition using free induction decays, the full width at half maximum

[Callaghan and Eccles, 1988; McFarland, 1992; Zhou, 1992] is

$$\Delta r_{\text{fr}} = 8 \left[ \frac{D(\ln 2)^2}{3\gamma G_{\text{fr}}} \right]^{1/3} \quad (15.7)$$

Compared with the case of the natural linewidth broadening (Equation 15.3), the resolution limit caused by diffusion varies slowly with the frequency-encoding gradient  $G_{\text{fr}}$ . Therefore, to improve resolution by a same factor, a much larger gradient is required. With the currently achievable gradient strength, the diffusion resolution limit is estimated to be 5 to 10  $\mu\text{m}$ .

### 15.2.2 Digital Resolution Limit

When the requirements imposed by intrinsic resolution limits are satisfied, image resolution is largely determined by the voxel size, provided that SNR is sufficient and the amplitude of physiologic motion is limited to a voxel. The voxel size, also known as digital resolution, can be calculated from the following equations:

*Frequency-encoding direction:*

$$\Delta x \equiv \frac{L_x}{N_x} = \frac{\Delta\nu}{2\pi\gamma G_x N_x} \quad (15.8)$$

*Phase-encoding direction:*

$$\Delta y \equiv \frac{L_y}{N_y} = \frac{\Delta\phi}{\gamma G_y t_{\text{pe}}} \quad (15.9)$$

where  $L$  is the field of view,  $N$  is the number of data points or the linear matrix size,  $G$  is the gradient strength,  $\Delta\nu$  is the receiver bandwidth,  $\Delta\phi$  is the phase range of the phase-encoding data (e.g., if the data cover a phase range from  $-\pi$  to  $+\pi$ , then  $\Delta\phi = 2\pi$ ), and the subscripts  $x$  and  $y$  represent frequency- and phase-encoding directions, respectively. To obtain a high digital resolution,  $L$  should be kept minimal, while  $N$  maximal. In practice, the minimal field of view and the maximal data points are constrained by other experimental parameters. In the frequency-encoding direction, decreasing field of view results in an increase in gradient amplitude at a constant receiver bandwidth or a decrease in the bandwidth for a constant gradient (Equation 15.8). Since the receiver bandwidth must be large enough to keep the acquisition of NMR signals within a certain time window, the largest available gradient strength thus imposes the digital resolution limit. In the phase-encoding direction,  $\Delta\phi$  is fixed at  $2\pi$  in most experiments, and the maximum  $t_{\text{pe}}$  value is refrained by the echo time. Thus digital resolution is also determined by the maximum available gradient, as indicated by Equation 15.9. It has been estimated that in order to achieve 1 mm resolution with a phase-encoding time of 4 msec, the required gradient strength is as high as 587 G/cm. This gradient requirement is beyond the range of current MR microscopes. Fortunately, the requirement is fully relaxed in projection acquisition where no phase encoding is involved.

### 15.2.3 Practical Resolution Limit

The intrinsic resolution limits predict that MR microscopy can theoretically reach the micron regime. To realize the resolution, one must overcome several technical obstacles. These obstacles, or practical resolution limits, include insufficient SNR, long data-acquisition times, and physiologic motion. At the current stage of development, these practical limitations are considerably more important than other resolution limits discussed earlier and actually determine the true image resolution.

SNR is of paramount importance in MR microscopy. As resolution improves, the total number of spins per voxel decreases drastically, resulting in a cubic decrease in signal intensity. When the voxel

signal intensity becomes comparable with noise level, structures become unresolvable even if the digital resolution and intrinsic resolution are adequate.

SNR in a voxel depends on many factors. The relationship between SNR and common experimental variables is given by

$$\text{SNR} \propto \frac{B_1 B_0^2 \sqrt{n}}{\sqrt{4kT \Delta\nu (R_{\text{coil}} + R_{\text{sample}})}} \quad (15.10)$$

where  $B_1$  is the RF magnetic field,  $B_0$  is the static magnetic field,  $n$  is the number of average,  $T$  is the temperature,  $\Delta\nu$  is the bandwidth,  $k$  is the Boltzmann constant, and  $R_{\text{coil}}$  and  $R_{\text{sample}}$  are the coil and sample resistance, respectively. When small RF coils are used,  $R_{\text{sample}}$  is negligible. Since  $R_{\text{coil}}$  is proportional to due to skin effects, the overall SNR increases as  $B_0^{7/4}$ . This result strongly suggests that MR microscopy be performed at high magnetic field. Another way to improve SNR is to increase the  $B_1$  field. This is accomplished by reducing the size of RF coils [McFarland and Mortara, 1992; Peck et al., 1990; Schoeniger et al., 1991; Zhou and Lauterbur, 1992]. Although increasing  $B_0$  and  $B_1$  is the most common approach to attacking the SNR problem, other methods such as signal averaging, pulse-sequence optimization, and post data processing are also useful in MR microscopy. For example, diffusion-induced signal loss can be effectively minimized using diffusion-reduced-gradient (DRG) echo pulse sequences [Cho et al., 1992]. Various forms of projection acquisition techniques [Gewalt et al., 1993; Hedges, 1984; McFarland and Mortara, 1992; Zhou and Lauterbur, 1992], as well as new  $k$ -space sampling schemes [Zhou et al., 1993], also have proved useful in SNR improvements. Recently, Black et al. [1993] used high-temperature superconducting materials for coil fabrication to simultaneously reduce coil resistance  $R_{\text{coil}}$  and coil temperature  $T$ . This novel approach can provide up to 70-fold SNR increase, equivalent to the SNR gain by increasing the magnetic field strength 11 times.

Long data-acquisition time is another practical limitation. Large image arrays, long repetition times (TR), and signal averaging all contribute to the overall acquisition time. For instance, a  $T_2$ -weighted image with a  $256^3$  image array requires a total acquisition time of more than 18 h (assuming TR = 500 msec and  $n = 2$ ). Such a long acquisition time is unacceptable for most applications. To reduce the acquisition time while still maintaining the desired contrast, fast-imaging pulse sequences such as echo-planar imaging (EPI) [Mansfield and Maudsley, 1977], driven equilibrium Fourier transform (DEFT) [Maki et al., 1988], fast low angle shot (FLASH) [Haase et al., 1986], gradient refocused acquisition at steady state (GRASS) [Karis et al., 1987], and rapid acquisition with relaxation enhancement (RARE) [Hennig et al., 1986] have been developed and applied to MR microscopy. The RARE pulse sequence, or fast spin-echo (FSE) [Mulkern et al., 1990], is particularly useful in high-field MR microscopy because of its insensitivity to magnetic susceptibility effects as well as the reduced diffusion loss [Zhou et al., 1993]. Using fast spin-echo techniques, a  $256^3$  image has been acquired in less than 2 h [Zhou et al., 1993].

For *in vivo* studies, the true image resolution is also limited by physiologic motion [Hedges, 1984; Wood and Henkelman, 1985]. Techniques to minimize the motion effects have been largely focused on pulse sequences and post data processing algorithms, including navigator echoes [Ehman and Felmler, 1989], motion compensation using even echo or moment nulling gradients, projection acquisition [Glover and Noll, 1993], and various kinds of ghost-image decomposition techniques [Xiang and Henkelman, 1991]. It should be noted, however, that by refining animal handling techniques and using synchronized data acquisition, physiologic motion effects can be effectively avoided and very high quality images can be obtained [Hedlund et al., 1986; Johnson et al., 1992].

### 15.3 Instrumentation

An MR microscope consists of a high-field magnet (>1.5 T), a set of gradient coils, an RF coil (or RF coils), and the associated RF systems, gradient power supplies, and computers. Among these components,

**FIGURE 15.1** A range of radiofrequency coils are used in MR microscopy. (a) A quadrature birdcage coil scaled to the appropriate diameter for rats (6 cm) is used for whole-body imaging. (b) Resonant coils have been constructed on microwave substrate that can be surgically implanted to provide both localization and improved SNR. (c) MR microscopy of specimens is accomplished with a modified Helmholtz coil providing good filling factors, high B homogeneity, and ease of access.

RF coils and gradient coils are often customized for specific applications in order to achieve optimal performance. Some general guidelines to design customized RF coils and gradient coils are presented below.

### 15.3.1 Radiofrequency Coils

Many types of RF coils can be used in MR microscopy (Figure 15.1). The choice of a particular coil configuration is determined by specific task and specimen size. If possible, the smallest coil size should always be chosen in order to obtain the highest SNR. For *ex-vivo* studies of tissue specimens, solenoid coils are a common choice because of their superior  $B_1$  field homogeneity, high sensitivity, as well as simplicity in fabrication. Using a 2.9 mm solenoid coil (5 turn), Zhou and Lauterbur [1992] have achieved the highest ever reported spatial resolution at  $6.4 \mu\text{m}^3$ . Solenoid coil configurations are also used by others to obtain images with similar resolution ( $\sim 10 \mu\text{m}$ ) [Cho et al., 1988; Hedges, 1984; McFarland and Mortara, 1992; Schoeniger et al., 1991]. Recently, several researchers began to develop microscopic solenoid coils with a size of a few hundred microns [McFarland and Mortara, 1992; Peck et al., 1990]. Fabrication of these microcoils often requires special techniques, such as light lithography and electron-beam lithography.

The direction of the  $B_1$  field generated by a solenoid coil prevents the coil from being coaxially placed in the magnet. Thus accessing and positioning samples are difficult. To solve this problem, Banson et al. [1992] devised a unique Helmholtz coil that consists of two separate loops. Each loop is made from a microwave laminate with a dielectric material sandwiched between two copper foils. By making use of the

distributed capacitance, the coil can be tuned to a desired frequency. Since the two loops of the coil are mechanically separated, samples can be easily slid into the gap between the loops without any obstruction. Under certain circumstances, the Helmholtz coil can outperform an optimally designed solenoid coil with similar dimensions.

For *in vivo* studies, although volume coils such as solenoid coils and birdcage coils can be employed, most high-resolution experiments are carried out using local RF coils, including surface coils [Banson et al., 1992; Rudin, 1987] and implanted coils [Farmer et al., 1989; Hollett et al., 1987; Zhou et al., 1994]. Surface coils can effectively reduce coil size and simultaneously limit the field of view to a small region of interest. They can be easily adaptable to the shape of samples and provide high sensitivity in the surface region. The problem of inhomogeneous  $B_1$  fields can be minimized using composite pulses [Hetherington et al., 1986] or adiabatic pulses [Ugurbil et al., 1987]. To obtain high-resolution images from regions distant from the surface, surgically implantable coils become the method of choice. These coils not only give better SNR than optimized surface coils [Zhou et al., 1992] but also provide accurate and consistent localization. The latter advantage is particularly useful for time-course studies on dynamic processes such as the development of pathology and monitoring the effects of therapeutic drugs.

The recent advent of high-temperature superconducting (HTS) RF coils has brought new excitement to MR microscopy [Black et al., 1993]. The substantial improvement, as discussed earlier, makes signal averaging unnecessary. Using these coils, the total imaging time will be solely determined by the efficiency to traverse the  $k$ -space. Although much research is yet to be done in this new area, combination of the HTS coils with fast-imaging algorithms will most likely provide a unique way to fully realize the potential of MR microscopy and eventually bring the technique into routine use.

### 15.3.2 Magnetic Field Gradient Coils

As discussed previously, high spatial resolution requires magnetic field gradients. The gradient strength increases proportional to the coil current and inversely proportional to the coil size. Since increasing current generates many undesirable effects (overheating, mechanical vibrations, eddy current, etc.), strong magnetic field gradient is almost exclusively achieved by reducing the coil diameter.

Design of magnetic field gradient coils for MR microscopy is a classic problem. Based on Maxwell equations, ideal surface current density can be calculated for a chosen geometry of the conducting surface. Two conducting surfaces are mostly used: a cylindrical surface parallel to the axis of the magnet and a cylindrical surface perpendicular to the axis. The ideal surface current density distributions for these two geometries are illustrated in Figure 15.2 [Suits and Wilken, 1989]. After the ideal surface current density distribution is obtained, design of gradient coils is reduced to a problem of using discrete conductors with a finite length to approximate the continuous current distribution function. The error in the approximation determines the gradient linearity. Recent advancements in computer-based fabrication and etching techniques have made it feasible to produce complicated current density distributions. Using these techniques, nonlinear terms up to the eleventh order can be eliminated over a predefined cylindrical volume.

Another issue in gradient coil design involves minimizing the gradient rise time so that fast-imaging techniques can be implemented successfully and short echo times can be achieved to minimize signal loss for short  $T_2$  specimens. The gradient rise time relies on three factors: the inductance over resistance ratio of the gradient coil, the time constant of the feedback circuit of the gradient power supply, and the decay rate of eddy current triggered by gradient switching. The time constant attributed to inductive resistance ( $L/R$ ) is relatively short ( $<100 \mu\text{sec}$ ) for most microscopy gradient coils, and the inductive resistance from the power supply can be easily adjusted to match the time constant of the coil. However, considering the high magnetic field gradient strength used in MR microscopy, eddy currents can be a serious problem. This problem is even worsened when the gradient coils are closely placed in a narrow magnet bore. To minimize the eddy currents, modern design of gradient coils uses an extra set of coils so that the eddy currents can be actively cancelled [Mansfield and Chapman, 1986]. Under close to optimal conditions,

**FIGURE 15.2** (a) Ideal surface current distributions to generate linear magnetic field gradients when the gradient coil former is parallel to the magnet bore: (b) for  $x$  gradient and (c) for  $z$  gradient. The analytical expressions for the current density distribution functions are  $J_x = KG_x[R \cos \theta (\sin \theta i - \cos \theta j) - z \sin \theta k]$  and  $J_z = KG_z Z [\sin \theta i - \cos \theta j]$ . The  $y$  gradient can be obtained by rotating  $J_x$   $90^\circ$ . (d) Ideal surface current distributions to generate linear magnetic field gradients when the gradient coil former is perpendicular to the magnet bore: (e) for  $x$  gradient and (f) for  $y$  gradient. The analytical expressions for the current density distribution functions are  $J_x = KG_x R (\sin 2\theta j)$  and  $J_y = KG_y (-R \cos^2 \theta i + y \sin \theta j + 0.5R \sin 2\theta k)$ . The  $z$  gradient can be obtained by rotating  $J_x$   $45^\circ$ . (The graphs are adapted based on Suits, B.H. and Wilken, D.E. [1989]. *J. Phys. E: Sci. Instrum.* 22: 565.)

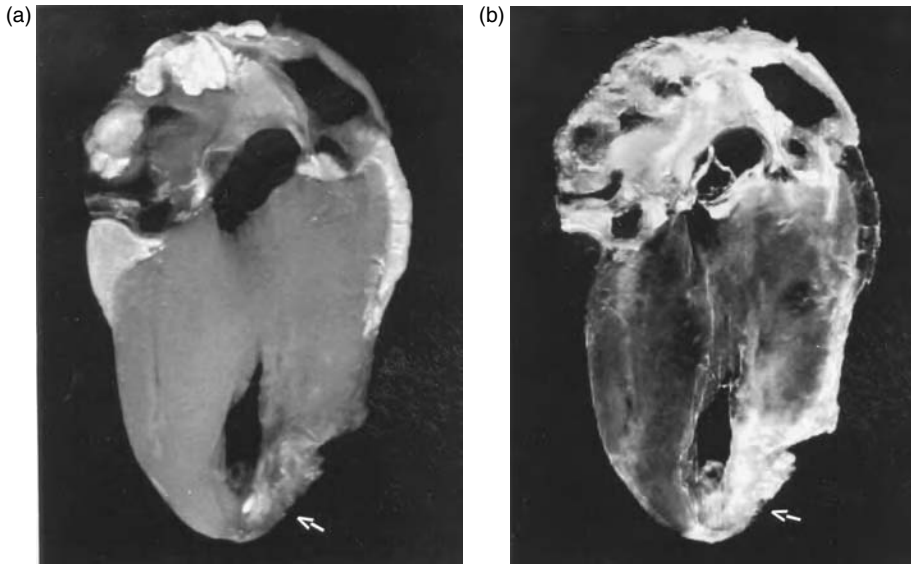

a rise time of  $<150 \mu\text{sec}$  can be achieved with a maximum gradient of 82 G/cm in a set of 8 cm coils [Johnson et al., 1992].

Although the majority of microscopic MR images are obtained using cylindrical gradient coils, surface gradient coils have been used recently in several studies [Cho et al., 1992]. Similar to surface RF coils, surface gradient coils can be easily adapted to the shape of samples and are capable of producing strong magnetic field gradient in limited areas. The surface gradient coils also provide more free space in the magnet, allowing easy access to samples. A major problem with surface gradient coils is the gradient nonlinearity. But when the region of interest is small, high-quality images can still be obtained with negligible distortions.

## 15.4 Applications

MR microscopy has a broad range of applications. We include here several examples. Figure 15.3 illustrates an application of MR microscopy in *ex vivo* histology. In this study, a fixed sheep heart with experimentally-induced infarct is imaged at 2T using 3D fast-spin-echo techniques with  $T_1$  (Figure 15.3a) and  $T_2$  (Figure 15.3b) contrasts. The infarct region is clearly detected in both images. The region of infarct can be segmented from the rest of the tissue and its volume can be accurately measured. Since the image is three-dimensional, the tissue pathology can be examined in any arbitrary orientation. The nondestructive nature of MR microscopy also allows the same specimen to be restudied using other techniques as well as using other contrast mechanisms of MR microscopy. Obtaining this dimension of information from conventional histologic studies would be virtually impossible.

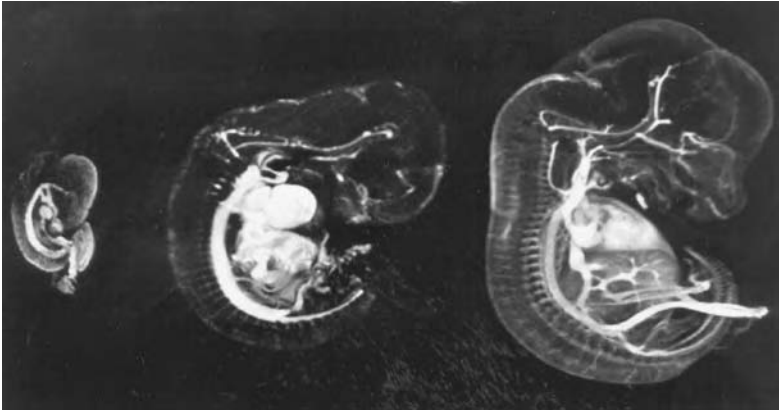

The *in vivo* capability of MR microscopy for toxicologic studies is illustrated in Figure 15.4. In this study [Farmer et al., 1989], the effect of mercuric chloride in rat kidney is monitored in a single animal. Therefore, development of tissue pathology over a time period is directly observed without the unnecessary

**FIGURE 15.3** Selected sections of 3D isotropic images of a sheep heart with experimentally induced infarct show the utility of MRM in pathology studies. A 3D FSE sequence has been designed to allow rapid acquisition of either (a)  $T_1$ -weighted or (b)  $T_2$ -weighted images giving two separate “stains” for the pathology. Arrows indicate areas of necrosis.

**FIGURE 15.4** Implanted RF coils allow *in vivo* studies of deep structures with much higher spatial resolution by limiting the field of view during excitation and by increasing the SNR over volume coils. An added benefit is the ability to accurately localize the same region during a time course study. Shown here is the same region of a kidney at four different time points following exposure to mercuric chloride. Note the description of boundaries between the several zones of the kidney in the early part of the study followed by regeneration of the boundaries upon repair.

**FIGURE 15.5** Isotropic 3D images of fixed mouse embryos at three stages of development have been volume rendered to allow visualization of the developing vascular anatomy.

interference arising from interanimal variabilities. Since the kidney was the only region of interest in this study, a surgically implanted coil was chosen to optimize SNR and to obtain consistent localization. Figure 15.4 shows four images obtained from the same animal at different time points to show the progression and regression of the  $\text{HgCl}_2$ -induced renal pathology. Tissue damage is first observed 24 h after the animal was treated by the chemical, as evident by the blurring between the cortex and the outer medulla. The degree of damage is greater in the image obtained at 48 h. Finally, at 360 h, the blurred boundary between the two tissue regions completely disappeared, indicating full recovery of the organ. The capability to monitor tissue pathologic changes *in vivo*, as illustrated in this example, bodes well for a broad range of applications in pharmacology, toxicology, and pathology.

Development biology is another area where MR microscopy has found an increasing number of applications, Jacobs and Fraser [1994] used MR microscopy to follow cell movements and lineages in developing frog embryos. In their study, 3D images of the developing embryo were obtained on a time scale faster than the cell division time and analyzed forward and backward in time to reconstruct full cell divisions and cell movements. By labeling a 16-cell embryo with an exogenous contrast agent (Gd-DTPA), they successfully followed the progression from early cleavage and blastula stage through gastrulation, neurulation, and finally to tail bud stage. More important, they found that external ectodermal and internal mesodermal tissues extend at different rates during amphibian gastrulation and neurulation. This and many other key events in vertebrate embryogenesis would be very difficult to observe with optical microscopy. Another example in developmental biology is given in Figure 15.5. Using 3D high-field (9.4-T) MR microscopy with large image arrays ( $256^3$ ), Smith et al. [1993] studied the early development of the circulatory system of mouse embryos. With the aid of a  $T_1$  contrast agent made from bovine serum albumin and Gd-DTPA, vasculature such as ventricles, atria, aorta, cardinal sinuses, basilar arteries, and thoracic arteries are clearly identified in mouse embryos at between 9.5 and 12.5 days of gestation. The ability to study embryonic development in a noninvasive fashion provided great opportunities to explore many problems in transgenic studies, gene targeting, and *in situ* hybridization.

In less than 10 yr, MR microscopy has grown from a scientific curiosity to a tool with a wide range of applications. Although many theoretical and experimental problems still exist at the present time, there is no doubt that MR microscopy will soon make a significant impact in many areas of basic research and clinical diagnosis.

## Further Information

A detailed description of the physics of NMR and MRI can be found in *Principles of Magnetic Resonance*, by C.S., Slichter (3rd edition, Springer-Verlag, 1989), in *NMR Imaging in Biology and Medicine*, by P. Morris (Clarendon Press, 1986), and in *Principles of Magnetic Resonance Microscopy*, by P.T., Callaghan (Oxford Press, 1991). The latter two books also contain detailed discussions on instrumentation, data acquisition, and image reconstruction for conventional and microscopic magnetic resonance imaging.

*Magnetic Resonance Microscopy*, edited by Blümich and Kuhn (VCH, 1992), is particularly helpful to understand various aspects of MR microscopy, both methodology and applications. Each chapter of the book covers a specific topic and is written by experts in the field.

*Proceedings of the Society of Magnetic Resonance* (formerly *Society of Magnetic Resonance in Medicine*, Berkeley, California), published annually, documents the most recent developments in the field of MR microscopy. *Magnetic Resonance in Medicine*, *Journal of Magnetic Resonance Imaging*, and *Magnetic Resonance Imaging*, all monthly journals, contain original research articles and are good sources for up-to-date developments.

### 16.1 Radiopharmaceuticals

---

*Thomas F. Budinger and Henry F. VanBrocklin*

Since the discovery of artificial radioactivity a half century ago, radiotracers, radionuclides, and radionuclide compounds have played a vital role in biology and medicine. Common to all is radionuclide (radioactive isotope) production. This section describes the basic ideas involved in radionuclide production and gives examples of the applications of radionuclides. The field of radiopharmaceutical chemistry has fallen into subspecialties of positron-emission tomography (PET) chemistry and general radiopharmaceutical chemistry, including specialists in technetium chemistry, taking advantage of the imaging attributes of technetium-99m.

The two general methods of radionuclide production are neutron addition (activation) from neutron reactors to make neutron-rich radionuclides which decay to give off electrons and gamma rays and charged-particle accelerators (linacs and cyclotrons) which usually produce neutron-deficient isotopes that decay by electron capture and emission of x-rays, gamma rays, and positrons. The production of artificial radionuclides is governed by the number of neutrons or charged particles hitting an appropriate target per time, the cross section for the particular reaction, the number of atoms in the target, and the

half-life of the artificial radionuclide:

$$A(t) = \frac{N\sigma\phi}{3.7 \times 10^{10}} \left(1 - e^{-0.693t/T_{1/2}}\right) \tag{16.1}$$

where  $A(t)$  is the produced activity in number of atoms per second,  $N$  is the number of target nuclei,  $\sigma$  is the cross section (probability that the neutron or charged particles will interact with the nucleus to form the artificial radioisotope) for the reaction,  $\phi$  is the flux of charged particles, and  $T_{1/2}$  is the half-life of the product. Note that  $N$  is the target mass divided by the atomic weight and multiplied by Avogadro's number ( $6.024 \times 10^{23}$ ) and  $\sigma$  is measured in  $\text{cm}^2$ . The usual flux is about  $10^{14}$  neutrons per sec or, for charged particles, 10 to 100 mA, which is equivalent to  $6.25 \times 10^{13}$  to  $6.25 \times 10^{14}$  charged particles per second.

### 16.1.1 Nuclear Reactor-Produced Radionuclides

Thermal neutrons of the order of  $10^{14}$  neutrons/sec/cm<sup>2</sup> are produced in a nuclear reactor usually during a controlled nuclear fission of uranium, though thorium or plutonium are also used. High specific activity neutron-rich radionuclides are produced usually through the (n, g), (n, p), or (n, a) reactions (Figure 16.1a). The product nuclides usually decay by  $\beta^-$  — followed by  $\gamma$ . Most of the reactor-produced radionuclides are produced by the (n, g) reaction. The final step in the production of a radionuclide consists of the separation of the product nuclide from the target container by chemical or physical means.

An alternative method for producing isotopes from a reactor is to separate the fission fragments from the spent fuel rods. This is the leading source of <sup>99</sup>Mo for medical applications. The following two methods of <sup>99</sup>Mo production are examples of carrier-added and no-carrier-added radionuclide synthesis, respectively. In Figure 16.1a, the <sup>99</sup>Mo is production from <sup>98</sup>Mo. Only a small fraction of the <sup>98</sup>Mo nuclei will be converted to <sup>99</sup>Mo. Therefore, at the end of neutron bombardment, there is a mixture of both isotopes. These are inseparable by conventional chemical separation techniques, and both isotopes would participate equally well in chemical reactions. The <sup>99</sup>Mo from fission of <sup>238</sup>U would not contain any other isotopes of Mo and is considered carrier-free. Thus radioisotopes produced by any means having the same atomic number as the target material would be considered carrier-added. Medical tracer techniques obviate the need for carrier-free isotopes.

### 16.1.2 Accelerator-Produced Radionuclides

Cyclotrons and linear accelerators (linacs) are sources of beams of protons, deuterons, or helium ions that bombarded targets to produce neutron-deficient (proton-rich) radionuclides (Figure 16.1b). The neutron-deficient radionuclides produced through these reactions are shown in Table 16.1. These product nuclides (usually carrier-free) decay either by electron capture or by positron emission tomography or both, followed by  $\gamma$  emission. In Table 16.2, most of the useful charged-particle reactions are listed.

**FIGURE 16.1** (a) High specific activity neutron-excess radionuclides are produced usually through the (n, g), (n, p) or (n, a) reactions. The product nuclides usually decay  $\beta^-$  — followed by  $\gamma$ . Most of the reactor produced radionuclides are produced by the (n, g) reaction. (b) Cyclotrons and linear accelerators (linacs) are sources of beams of protons, deuterons, or helium ions which bombard targets to produce neutron-deficient radionuclides.

**TABLE 16.1** Radionuclides Used in Biomedicine

Radionuclide	Half-life	Application(s)
Arsenic-74*	17.9 d	A positron emitting chemical analog of phosphorus
Barium-128*	2.4 d	Parent in the generator system for producing the positron emitting $^{128}\text{Cs}$ , a potassium analog
Beryllium-7*	53.37 d	Berylliosis studies
Bromine-77	57 h	Radioimmunotherapy
Bromine-82	35.3 h	Used in metabolic studies and studies of estrogen receptor content
Carbon-11*	20.3 min	Positron emitter for metabolism imaging
Cobalt-57*	270 d	Calibration of imaging instruments
Copper-62	9.8 min	Heart perfusion
Copper-64	12.8 h	Used as a clinical diagnostic agent for cancer and metabolic disorders
Copper-67	58.5 h	Radioimmunotherapy
Chromium-51	27.8 d	Used to assess red blood cell survival
Fluorine-18	109.7 min	Positron emitter used in glucose analogs uptake and neuroreceptor imaging
Gallium-68	68 min	Required in calibrating PET tomographs. Potential antibody level
Germanium-68*	287 d	Parent in the generator system for producing the positron emitting $^{68}\text{Ga}$
Indium-111*	2.8 d	Radioimmunotherapy
Iodine-122	3.76 min	Positron emitter for blood flow studies
Iodine-123*	13.3 h	SPECT brain imaging agent
Iodine-124*	4.2 d	Radioimmunotherapy, positron emitter
Iodine-125	60.2 d	Used as a potential cancer therapeutic agent
Iodine-131	8.1 d	Used to diagnose and treat thyroid disorders including cancer
Iron-52*	8.2 h	Used as an iron tracer, positron emitter for bone-marrow imaging
Magnesium-28*	21.2 h	Magnesium tracer which decays to $^{28}\text{Al}$
Magnesium-52m	5.6 d	Flow tracer for heart muscle
Mercury-195m*	40 h	Parent in the generator system for producing $^{195\text{m}}\text{Au}$ , which is used in cardiac blood pool studies
Molybdenum-99	67 h	Used to produce technetium-99m, the most commonly used radioisotope in clinical nuclear medicine
Nitrogen-13*	9.9 min	Positron emitter used as $^{13}\text{NH}$ for heart perfusion studies
Osmium-191	15 d	Decays to iridium-191 used for cardiac studies
Oxygen-15*	123 s	Positron emitter used for blood flow studies as $\text{H}_2^{15}\text{O}$
Palladium-103	17 d	Used in the treatment of prostate cancer
Phosphorus-32	14.3 d	Used in cancer treatment, cell metabolism and kinetics, molecular biology, genetics research, biochemistry, microbiology, enzymology, and as a starter to make many basic chemicals and research products
Rhenium-188	17 h	Used for treatment of medullary thyroid carcinoma and alleviation of pain in bone metastases
Rubidium-82*	1.2 min	Positron emitter used for heart perfusion studies
Ruthenium-97*	2.9 d	Hepatobiliary function, tumor and inflammation localization
Samarium-145	340 d	Treatment of ocular cancer
Samarium-153	46.8 h	Used to radiolabel various molecules as cancer therapeutic agents and to alleviate bone cancer pain
Scandium-47	3.4 d	Radioimmunotherapy
Scandium-47*	3.4 d	Used in the therapy of cancer
Strontium-82*	64.0 d	Parent in the generator system for producing the positron emitting $^{82}\text{Rb}$ , a potassium analogue
Strontium-85	64 d	Used to study bone formation metabolism
Strontium-89	52 d	Used to alleviate metastatic bone pain
Sulfur-35	87.9 d	Used in studies of cell metabolism and kinetics, molecular biology, genetics research, biochemistry, microbiology, enzymology, and as a start to make many basic chemicals and research products
Technetium-99m	6 h	The most widely used radiopharmaceutical in nuclear medicine and produced from molybdenum-99
Thallium-201*	74 h	Cardiac imaging agent
Tin-117m	14.0 d	Palliative treatment of bone cancer pain

(Continued)

**TABLE 16.1** (Continued) Radionuclides Used in Biomedicine

Radionuclide	Half-life	Application(s)
Tritium (hydrogen-3)	12.3 yr	Used to make tritiated water which is used as a starter for thousands of different research products and basic chemicals; used for life science and drug metabolism studies to ensure the safety of potential new drugs
Tungsten-178*	21.5 d	Parent in generator system for producing <sup>178</sup> Ta, short-lived scanning agent
Tungsten-188	69 d	Decays to rhenium-188 for treatment of cancer and rheumatoid arthritis
Vanadium-48*	16.0 d	Nutrition and environmental studies
Xenon-122*	20 h	Parent in the generator system for producing the positron emitting <sup>122</sup> I
Xenon-127*	36.4 d	Used in lung ventilation studies
Xenon-133	5.3 d	Used in lung ventilation and perfusion studies
Yttrium-88*	106.6 d	Radioimmunotherapy
Yttrium-90	64 h	Used to radiolabel various molecules as cancer therapeutic agents
Zinc-62*	9.13 h	Parent in the generator system for producing the positron emitting <sup>62</sup> Cu
Zirconium-89*	78.4 h	Radioimmunotherapy, positron emitter

\* Produced by accelerated charged particles. Others are produced by neutron reactors.

**FIGURE 16.2** <sup>99m</sup>Tc-Sestamibi is a radiopharmaceutical used to evaluate myocardial perfusion or in the diagnosis of cancer using both computed tomography and scintigraphy techniques.

**TABLE 16.2** Important Reactions for Cyclotron-Produced Radioisotopes

1. $p, n$	7. $p, pn$
2. $p, 2n$	8. $p, 2p$
3. $d, n$	9. $d, p$
4. $d, 2n$	10. $d, ^4\text{He}$
5. $d, ^4\text{He}$	11. $p, d$
6. $d, ^4\text{He}, n$	12. $^4\text{He}, n$
13. $^3\text{He}, p$	

The heat produced by the beam current on the target material can interfere with isotope production and requires efficient heat-removal strategies using extremely stable heat-conducting target materials such as metal foils, electroplated metals, metal powders, metal oxides, and salts melted on duralmin plate. All the modern targets use circulating cold deionized water and chilled helium gas to aid in cooling the

target body and window foils. Cyclotrons used in medical studies have  $^{11}\text{C}$ ,  $^{13}\text{N}$ ,  $^{15}\text{O}$ , and  $^{18}\text{F}$  production capabilities that deliver the product nuclides on demand through computer-executed commands. The radionuclide is remotely transferred into a lead-shielded hot cell for processing. The resulting radionuclides are manipulated using microscale radiochemical techniques: small-scale synthetic methodology, ion-exchange chromatography, solvent extraction, electrochemical synthesis, distillation, simple filtration, paper chromatography, and isotopic carrier precipitation. Various relevant radiochemical techniques have been published in standard texts.

### 16.1.3 Generator-Produced Radionuclides

If the reactor, cyclotron, or natural product radionuclide of long half-life decays to a daughter with nuclear characteristics appropriate for medical application, the system is called a medical radionuclide generator. There are several advantages afforded by generator-produced isotopes. These generators represent a convenient source of short-lived medical isotopes without the need for an on-site reactor or particle accelerator. Generators provide delivery of the radionuclide on demand at a site remote from the production facility. They are a source of both gamma- and positron-emitting isotopes.

The most common medical radionuclide generator is the  $^{99}\text{Mo} \text{ \AE } ^{99\text{m}}\text{Tc}$  system, the source of  $^{99\text{m}}\text{Tc}$ , a gamma-emitting isotope currently used in 70% of the clinical nuclear medicine studies. The  $^{99}\text{Mo}$  has a 67-h half-life, giving this generator a useful life of about a week. Another common generator is the  $^{68}\text{Ge} \text{ \AE } ^{68}\text{Ga}$  system. Germanium (half-life is 287 d) is accelerator-produced in high-energy accelerators (e.g., BLIP, LAMPE, TRIUMF) through the alpha-particle bombardment of  $^{66}\text{Zn}$ . The  $^{68}\text{Ge}$  decays to  $^{68}\text{Ga}$ , a positron emitter, which has a 68-min half-life. Gallium generators can last for several months.

The generator operation is fairly straightforward. In general, the parent isotope is bound to a solid chemical matrix (e.g., alumina column, anionic resin, Donux resin). As the parent decays, the daughter nuclide grows in. The column is then flushed (“milked”) with a suitable solution (e.g., saline, hydrochloric acid) that elutes the daughter and leaves the remaining parent absorbed on the column. The eluent may be injected directly or processed into a radiopharmaceutical.

### 16.1.4 Radiopharmaceuticals

$^{99\text{m}}\text{Tc}$  is removed from the generator in the form of  $\text{TcO}_4^-$  (pertechnetate). This species can be injected directly for imaging or incorporated into a variety of useful radiopharmaceuticals. The labeling of  $^{99\text{m}}\text{Tc}$  usually involves reduction complexation/chelation.  $^{99\text{m}}\text{Tc}$ -Sestamibi (Figure 16.2) is a radiopharmaceutical used to evaluate myocardial perfusion or to diagnose cancer. There are several reduction methods employed, including Sn(II) reduction in  $\text{NaHCO}_3$  at pH of 8 and other reduction and complexation reactions such as  $\text{S}_2\text{O}_3 + \text{HCl}$ ,  $\text{FeCl}_3 + \text{ascorbic acid}$ ,  $\text{LiBH}_4$ ,  $\text{Zn} + \text{HCl}$ ,  $\text{HCl}$ ,  $\text{Fe(II)}$ ,  $\text{Sn(II)F}_2$ ,  $\text{Sn(II) citrate}$ , and  $\text{Sn(II) tartrate}$  reduction and complexation, electrolytic reduction, and *in vivo* labeling of red cells following Sn(II) pyrophosphate or Sn(II) DTPA administration.  $^{131}\text{I}$ ,  $^{125}\text{I}$ , and  $^{123}\text{I}$  labeling requires special reagents or conditions such as chloramine-T, widely used for protein labeling at 7.5 pH; peroxidase +  $\text{H}_2\text{O}_2$  widely used for radioassay tracers; isotopic exchange for imaging tracers; excitation labeling as in  $^{123}\text{Xe} \text{ \AE } ^{123}\text{I}$  diazotization plus iodination for primary amines; conjugation labeling with Bolton Hunter agent (N-succinimidyl 3-[4-hydroxy 5-( $^{131,125,123}\text{I}$ )iodophenyl] propionate); hydroboration plus iodination; electrophilic destannylation; microdiffusion with fresh iodine vapor; and other methods. Radiopharmaceuticals in common use for brain perfusion studies are N-isopropyl-p [ $^{123}\text{I}$ ] iodoamphetamine and  $^{99\text{m}}\text{Tc}$ -labeled hexamethylpropyleneamine.

### 16.1.5 PET Radionuclides

For  $^{11}\text{C}$ ,  $^{13}\text{N}$ ,  $^{15}\text{O}$ , and  $^{18}\text{F}$ , the modes of production of short-lived positron emitters can dictate the chemical form of the product, as shown in Table 16.3. Online chemistry is used to make various PET agents and precursors. For example,  $^{11}\text{C}$  cyanide, an important precursor for synthesis of other labeled compounds, is produced in the cyclotron target by first bombarding  $\text{N}_2 + 5\% \text{ H}_2$  gas target with 20-MeV

**TABLE 16.3** Major Positron-Emitting Radionuclides Produced by Accelerated Protons

Radionuclide	Half-Life	Reaction
Carbon-11	20 min	$^{12}\text{C} (p, pn) ^{11}\text{C}$
		$^{14}\text{N} (p, \alpha) ^{11}\text{C}$

		$^{20}\text{Ne} (d, \alpha) ^{18}\text{F}$

Note:  $A(x, y)B$ :  $A$  is target,  $x$  is the bombarding particle,  $y$  is the radiation product, and  $B$  is the isotope produced.

**FIGURE 16.3** Schematic for the chemical production of deoxyglucose labeled with fluorine-18. Here  $\text{K}_{222}$  refers to Kryptofix and  $\text{C}_{18}$  denotes a reverse-phase high-pressure liquid chromatography column.

protons. The product is carbon-labeled methane,  $^{11}\text{CH}_4$ , which when combined with ammonia and passed over a platinum wool catalyst at  $1000^\circ\text{C}$  becomes  $^{11}\text{CN}^-$ , which is subsequently trapped in  $\text{NaOH}$ .

Molecular oxygen is produced by bombarding a gas target of  $^{14}\text{N}_2 + 2\% \text{O}_2$  with deuterons (6 to 8 MeV). A number of products (e.g.,  $^{15}\text{O}_2$ ,  $\text{C}^{15}\text{O}_2$ ,  $\text{N}^{15}\text{O}_2$ ,  $^{15}\text{O}_3$ , and  $\text{H}_2^{15}\text{O}$ ) are trapped by soda lime followed by charcoal to give  $^{15}\text{O}_2$  as the product. However, if an activated charcoal trap at  $900^\circ\text{C}$  is used before the soda lime trap, the  $^{15}\text{O}_2$  will be converted to  $\text{C}^{15}\text{O}$ . The specific strategies for other online PET agents is given in Rayudu [1990].

Fluorine-18 ( $^{18}\text{F}$ ) is a very versatile positron emitting isotope. With a 2-h half-life and two forms ( $\text{F}^+$  and  $\text{F}^-$ ), one can develop several synthetic methods for incorporating  $^{18}\text{F}$  into medically useful compounds [Kilbourn, 1990]. Additionally, fluorine forms strong bonds with carbon and is roughly the same size as a hydrogen atom, imparting metabolic and chemical stability of the molecules without drastically altering biologic activity. The most commonly produced  $^{18}\text{F}$  radiopharmaceutical is 2-deoxy-2- $^{18}\text{F}$ fluoroglucose (FDG). This radiotracer mimics part of the glucose metabolic pathway and has shown both hypo- and hypermetabolic abnormalities in cardiology, oncology, and neurology. The synthetic pathway for the production of FDG is shown in Figure 16.3.

The production of positron radiopharmaceuticals requires the rapid incorporation of the isotope into the desired molecule. Chemical techniques and synthetic strategies have been developed to facilitate these reactions. Many of these synthetic manipulations require hands-on operations by a highly trained chemist. Additionally, since positrons give off 2- to 511-keV gamma rays upon annihilation, proximity

to the source can increase one's personal dose. The demand for the routine production of positron radiopharmaceuticals such as FDG has led to the development of remote synthetic devices. These devices can be human-controlled (i.e., flipping switches to open air-actuated valves), computer-controlled, or robotic. A sophisticated computer-controlled chemistry synthesis unit has been assembled for the fully automated production of  $^{18}\text{F}$ FDG [Padgett, 1989]. A computer-controlled robot has been programmed to produce 6a- $^{18}\text{F}$ fluoroestradiol for breast cancer imaging [Brodack et al., 1986; Mathias et al., 1987]. Both these types of units increase the availability and reduce the cost of short-lived radiopharmaceutical production through greater reliability and reduced need for a highly trained staff. Additionally, these automated devices reduce personnel radiation exposure. These and other devices are being designed with greater versatility in mind to allow a variety of radiopharmaceuticals to be produced just by changing the programming and the required reagents.

These PET radionuclides have been incorporated into a wide variety of medically useful radiopharmaceuticals through a number of synthetic techniques. The development of PET scanner technology has added a new dimension to synthetic chemistry by challenging radiochemists to devise labeling and purification strategies that proceed on the order of minutes rather than hours or days as in conventional synthetic chemistry. To meet this challenge, radiochemists are developing new target systems to improve isotope production and sophisticated synthetic units to streamline routine production of commonly desired radiotracers as well as preparing short-lived radiopharmaceuticals for many applications.

## 16.2 Instrumentation

*Thomas F. Budinger*

### 16.2.1 Background

The history of positron-emission tomography (PET) can be traced to the early 1950s, when workers in Boston first realized the medical imaging possibilities of a particular class of radioactive substances. It was recognized then that the high-energy photons produced by annihilation of the positron from positron-emitting isotopes could be used to describe, in three dimensions, the physiologic distribution of “tagged” chemical compounds. After two decades of moderate technological developments by a few research centers, widespread interest and broadly based research activity began in earnest following the development of sophisticated reconstruction algorithms and improvements in detector technology. By the mid-1980s, PET had become a tool for medical diagnosis and for dynamic studies of human metabolism.

Today, because of its million-fold sensitivity advantage over magnetic resonance imaging (MRI) in tracer studies and its chemical specificity, PET is used to study neuroreceptors in the brain and other body tissues. In contrast, MRI has exquisite resolution for anatomic (Figure 16.4) and flow studies as well as unique attributes of evaluating chemical composition of tissue but in the millimolar range rather than the nanomolar range of much of the receptor proteins in the body. Clinical studies include tumors of the brain, breast, lungs, lower gastrointestinal tract, and other sites. Additional clinical uses include Alzheimer’s disease, Parkinson’s disease, epilepsy, and coronary artery disease affecting heart muscle metabolism and flow. Its use has added immeasurably to our current understanding of flow, oxygen utilization, and the metabolic changes that accompany disease and that change during brain stimulation and cognitive activation.

### 16.2.2 PET Theory

PET imaging begins with the injection of a metabolically active tracer — a biologic molecule that carries with it a positron-emitting isotope (e.g.,  $^{11}\text{C}$ ,  $^{13}\text{N}$ ,  $^{15}\text{O}$ , or  $^{18}\text{F}$ ). Over a few minutes, the isotope accumulates in an area of the body for which the molecule has an affinity. As an example, glucose labeled with  $^{11}\text{C}$ , or a glucose analogue labeled with  $^{18}\text{F}$ , accumulates in the brain or tumors, where glucose is used as the primary source of energy. The radioactive nuclei then decay by positron emission. In positron (positive electron) emission, a nuclear proton changes into a positive electron and a neutron. The atom maintains its atomic mass but decreases its atomic number by 1. The ejected positron combines with an electron almost instantaneously, and these two particles undergo the process of annihilation. The energy associated with

**FIGURE 16.4** The MRI image shows the arteriovenous malformation (AVM) as an area of signal loss due to blood flow. The PET image shows the AVM as a region devoid of glucose metabolism and also shows decreased metabolism in the adjacent frontal cortex. This is a metabolic effect of the AVM on the brain and may explain some of the patient’s symptoms.

**FIGURE 16.5** The physical basis of positron-emission tomography. Positrons emitted by “tagged” metabolically active molecules annihilate nearby electrons and give rise to a pair of high-energy photons. The photons fly off in nearly opposite directions and thus serve to pinpoint their source. The biologic activity of the tagged molecule can be used to investigate a number of physiologic functions, both normal and pathologic.

the masses of the positron and electron particles is 1.022 MeV in accordance with the energy  $E$  to mass  $m$  equivalence  $E = mc^2$ , where  $c$  is the velocity of light. This energy is divided equally between two photons that fly away from one another at a 180-degree angle. Each photon has an energy of 511 keV. These high-energy gamma rays emerge from the body in opposite directions, to be detected by an array of detectors that surround the patient (Figure 16.5). When two photons are recorded simultaneously by a pair of detectors, the annihilation event that gave rise to them must have occurred somewhere along the line connecting the detectors. Of course, if one of the photons is scattered, then the line of coincidence will be incorrect. After 100,000 or more annihilation events are detected, the distribution of the positron-emitting tracer is calculated by tomographic reconstruction procedures. PET reconstructs a two-dimensional (2D) image from the one-dimensional projections seen at different angles. Three-dimensional (3D) reconstructions also can be done using 2D projections from multiple angles.

### 16.2.3 PET Detectors

Efficient detection of the annihilation photons from positron emitters is usually provided by the combination of a crystal, which converts the high-energy photons to visible-light photons, and a photomultiplier tube that produces an amplified electric current pulse proportional to the amount of light photons interacting with the photocathode. The fact that imaging system sensitivity is proportional to the square of the detector efficiency leads to a very important requirement that the detector be nearly 100% efficient. Thus other detector systems such as plastic scintillators or gas-filled wire chambers, with typical individual efficiencies of 20% or less, would result in a coincident efficiency of only 4% or less.

Most modern PET cameras are multilayered with 15 to 47 levels or transaxial layers to be reconstructed (Figure 16.6). The lead shields prevent activity from the patient from causing spurious counts in the tomograph ring, while the tungsten septa reject some of the events in which one (or both) of the 511-keV photons suffer a Compton scatter in the patient. The sensitivity of this design is improved by collection of data from cross-planes (Figure 16.6). The arrangement of scintillators and phototubes is shown in Figure 16.7.

The “individually coupled” design is capable of very high resolution, and because the design is very parallel (all the photomultiplier tubes and scintillator crystals operate independently), it is capable of very high data throughput. The disadvantages of this type of design are the requirement for many expensive

**FIGURE 16.6** Most modern PET cameras are multilayered with 15 to 47 levels or transaxial layers to be reconstructed. The lead shields prevent activity from the patient from causing spurious counts in the tomograph ring, while the tungsten septa reject some of the events in which one (or both) of the 511-keV photons suffer a Compton scatter in the patient. The sensitivity of this design is improved by collection of data from cross-planes.

**FIGURE 16.7** The arrangement of scintillators and phototubes is shown. The “individually coupled” design is capable of very high resolution, and because the design is very parallel (all the photomultiplier tubes and scintillator crystals operate independently), it is capable of very high data throughput. A block detector couples several photomultiplier tubes to a bank of scintillator crystals and uses a coding scheme to determine the crystal of interaction. In the two-layer block, five photomultiplier tubes are coupled to eight scintillator crystals.

**FIGURE 16.8** Factors contributing to the resolution of the PET tomograph. The contribution most accessible to further reduction is the size of the detector crystals.

photomultiplier tubes and, additionally, that connecting round photomultiplier tubes to rectangular scintillation crystals leads to problems of packing rectangular crystals and circular phototubes of sufficiently small diameter to form a solid ring.

The contemporary method of packing many scintillators for 511 keV around the patient is to use what is called a block detector design. A block detector couples several photomultiplier tubes to a bank of scintillator crystals and uses a coding scheme to determine the crystal of interaction. In the two-layer block (Figure 16.7), five photomultiplier tubes are coupled to eight scintillator crystals. Whenever one of the outside four photomultiplier tubes fires, a 511-keV photon has interacted in one of the two crystals attached to that photomultiplier tube, and the center photomultiplier tube is then used to determine whether it was the inner or outer crystal. This is known as a digital coding scheme, since each photomultiplier tube is either “hit” or “not hit” and the crystal of interaction is determined by a “digital” mapping of the hit pattern. Block detector designs are much less expensive and practical to form into a multilayer camera. However, errors in the decoding scheme reduce the spatial resolution, and since the entire block is “dead” whenever one of its member crystals is struck by a photon, the dead time is worse than with individual coupling. The electronics necessary to decode the output of the block are straightforward but more complex than that needed for the individually coupled design.

Most block detector coding schemes use an analog coding scheme, where the ratio of light output is used to determine the crystal of interaction. In the example above, four photomultiplier tubes are coupled to a block of BGO that has been partially sawed through to form 64 “individual” crystals. The depth of the cuts are critical; that is, deep cuts tend to focus the scintillation light onto the face of a single photomultiplier tube, while shallow cuts tend to spread the light over all four photomultiplier tubes. This type of coding scheme is more difficult to implement than digital coding, since analog light ratios place more stringent requirements on the photomultiplier tube linearity and uniformity as well as scintillator crystal uniformity. However, most commercial PET cameras use an analog coding scheme because it is much less expensive due to the lower number of photomultiplier tubes required.

**FIGURE 16.9** The evolution of resolution. Over the past decade, the resolving power of PET has improved from about 9 to 2.6 mm. This improvement is graphically illustrated by the increasing success with which one is able to resolve “hot spots” of an artificial sample that are detected and imaged by the tomographs.

### 16.2.4 Physical Factors Affecting Resolution

The factors that affect the spatial resolution of PET tomographs are shown in Figure 16.8. The size of the detector is critical in determining the system’s geometric resolution. If the block design is used, there is a degradation in this geometric resolution by 2.2 mm for BGO. The degradation is probably due to the limited light output of BGO and the ratio of crystals (cuts) per phototube.

The angle between the paths of the annihilation photons can deviated from 180 degrees as a result of some residual kinetic motion (Fermi motion) at the time of annihilation. The effect on resolution of this deviation increases as the detector ring diameter increases so that eventually this factor can have a significant effect.

The distance the positron travels after being emitted from the nucleus and before annihilation causes a deterioration in spatial resolution. This distance depends on the particular nuclide. For example, the range of blurring for <sup>18</sup>F, the isotope used for many of the current PET studies, is quite small compared with that of the other isotopes. Combining values for these factors for the PET-600 tomograph, we can estimate a detector-pair spatial resolution of 2.0 mm and a reconstructed image resolution of 2.6 mm. The measured resolution of this system is 2.6 mm, but most commercially available tomographs use a block detector design (Figure 16.7), and the resolution of these systems is above 5 mm. The evolution of resolution improvement is shown in Figure 16.9.

The resolution evolutions discussed above pertain to results for the center or axis of the tomograph. The resolution at the edge of the object (e.g., patient) will be less by a significant amount due to two factors. First, the path of the photon from an “off-center” annihilation event typically traverses more than one detector crystal, as shown in Figure 16.10. This results in an elongation of the resolution spread function along the radius of the transaxial plane. The loss of resolution is dependent on the crystal density and the diameter of the tomograph detector ring. For a 60-cm diameter system, the resolution can deteriorate by a factor of 2 from the axis to 10 cm.

The coincidence circuitry must be able to determine coincident events with 10- to 20-nsec resolution for each crystal–crystal combination (i.e., chord). The timing requirement is set jointly by the time of flight across the detector ring (4 nsec) and the crystal-to-crystal resolving time (typically 3 nsec). The most stringent requirement, however, is the vast number of chords in which coincidences must be determined (over 1.5 million in a 24-layer camera with septa in place and 18 million with the septa removed).

It is obviously impractical to have an individual coincidence circuit for each chord, so tomograph builders use parallel organization to solve this problem. A typical method is to use a high-speed clock

**FIGURE 16.10** Resolution astigmatism in detecting off-center events. Because annihilation photons can penetrate crystals to different depths, the resolution is not equal in all directions, particularly at the edge of the imaging field. This problem of astigmatism will be taken into account in future PET instrumentation.

(typically 200 MHz) to mark the arrival time of each 511-keV photon and a digital coincidence processor to search for coincident pairs of detected photons based on this time marker. This search can be done extremely quickly by having multiple sorters working in parallel.

The maximum event rate is also quite important, especially in septaless systems. The maximum rate in a single detector crystals is limited by the dead time due to the scintillator fluorescent lifetime (typically 1 msec per event), but as the remainder of the scintillator crystals are available, the instrument has much higher event rates (e.g., number of crystals  $\times$  1 msec). Combining crystals together to form contiguous blocks reduces the maximum event rate because the fluorescent lifetime applies to the entire block and a fraction of the tomograph is dead after each event.

### 16.2.5 Random Coincidences

If two annihilation events occurs within the time resolution of the tomograph (e.g., 10 nsec), then random coincident “events” add erroneous background activity to the tomograph and are significant at high event rates. These can be corrected for on a chord-by-chord basis. The noncoincidence event rate of each crystal pair is measured by observing the rate of events beyond the coincident timing window. The random rate for the particular chord  $R_{ij}$  corresponding to a crystal pair is

$$R_{ij} = r_i \times r_j \times 2\tau \quad R_{ij} = R_{ij} \tag{16.2}$$

where  $r_i$  and  $r_j$  are the event rates of crystal  $i$  and crystal  $j$ , and  $\tau$  is the coincidence window width. As the activity in the subject increases, the event rate in each detector increases. Thus the random event rate will increase as the square of the activity.

### 16.2.6 Tomographic Reconstruction

Before reconstruction, each projection ray or chord receives three corrections: crystal efficiency, attenuation, and random efficiency. The efficiency for each chord is computed by dividing the observed count rate for that chord by the average court rate for chords with a similar geometry (i.e., length). This is typically done daily using a transmission source without the patient or object in place. Once the patient is in position in the camera, a transmission scan is taken, and the attenuation factor for each chord is computed by dividing its transmission count rate by its efficiency count rate. The patient is then injected with the

isotope, and an emission scan is taken, during which time the random count rate is also measured. For each chord, the random event rate is subtracted from the emission rate, and the difference is divided by the attenuation factor and the chord efficiency. (The detector efficiency is divided twice because two separate detection's measurements are made — transmission and emission.) The resulting value is reconstructed, usually with the filtered backprojection algorithm. This is the same algorithm used in x-ray computed tomography (CT) and in projection MRI. The corrected projection data are formatted onto parallel- or fan-beam data sets for each angle. These are modified by a high-pass filter and backprojected.

The process of PET reconstruction is linear and shown by operators successively operating on the projection  $P$ :

$$A = \sum_{\theta} BPF^{-1}RF(P) \tag{16.3}$$

where  $A$  is the image,  $F$  is the Fourier transform,  $R$  is the ramp-shaped high-pass filter,  $F^{-1}$  is the inverse Fourier transform,  $BP$  is the backprojection operation, and  $\theta$  denotes the superposition operation.

The alternative class of reconstruction algorithms involves iterative solutions to the classic inverse problem:

$$P = FA \tag{16.4}$$

where  $P$  is the projection matrix,  $A$  is the matrix of true data being sought, and  $F$  is the projection operation. The inverse is

$$A = F^{-1}P \tag{16.4a}$$

which is computed by iteratively estimating the data  $A'$  and modifying the estimate by comparison of the calculated projection set  $P'$  with the true observed projections  $P$ . The expectation-maximization algorithm solves the inverse problem by updating each pixel value  $a_i$  in accord with

$$a_i^{k+1} = \sum_j P_j \frac{a_j^k f_{ij}}{\sum_i a_i^k f_{ij}} \tag{16.5}$$

where  $P$  is the measured projection,  $f_{ij}$  is the probability a source at pixel  $i$  will be detected in projection detector  $j$ , and  $k$  is the iteration.

### 16.2.7 Sensitivity

The sensitivity is a measure of how efficiently the tomograph detects coincident events and has units of count rate per unit activity concentration. It is measured by placing a known concentration of radionuclide in a water-filled 20-cm-diameter cylinder in the field of view. This cylinder, known as a phantom, is placed in the tomograph, and the coincidence event rate is measured. High sensitivity is important because emission imaging involves counting each event, and the resulting data are as much as 1000 times less than experienced in x-ray CT. Most tomographs have high individual detection efficiency for 511-keV photons impinging on the detector (>90%), so the sensitivity is mostly determined by geometric factors, that is, the solid angle subtended by the tomograph:

$$S = \frac{A\varepsilon^2\gamma \times 3.7 \times 10^4}{4\pi r^2} (\text{events/sec})/(\text{mCi/cc}) \tag{16.6}$$

where:

- $r$  = radius of tomograph
- $A$  = area of detector material seen by each point in the object ( $2\pi r \times$  axial aperture)
- $\varepsilon$  = efficiency of scintillator
- $\gamma$  = attenuation factor

For a single layer, the sensitivity of a tomograph of 90 cm diameter (2-cm axial crystals) will be 15,000 events/sec/mCi/ml for a disk of activity 20 cm in diameter and 1 cm thick. For a 20-cm-diameter cylinder, the sensitivity will be the same for a single layer with shields or septa that limit the off-slice activity from entering the collimators. However, modern multislice instruments use septa that allow activity from adjacent planes to be detected, thus increasing the solid angle and therefore the sensitivity. This increase comes at some cost due to increase in scatter. The improvement in sensitivity is by a factor of 7, but after correction for the noise, the improvement is 4. The noise equivalent sensitivity  $S_{NE}$  is given by

$$S_{NE} = \frac{(\text{true events})^2}{\text{true} \times \text{scatter} \times \text{random}} \tag{16.7}$$

### 16.2.8 Statistical Properties of PET

The ability to map quantitatively the spatial distribution of a positron-emitting isotope depends on adequate spatial resolution to avoid blurring. In addition, sufficient data must be acquired to allow a

**FIGURE 16.11** Statistical requirements and spatial resolution. The general relationship between the detected number of events and the number of resolution elements in an image is graphed for various levels of precision. These are relations for planes of constant thickness.

statistically reliable estimation of the tracer concentration. The amount of available data depends on the biomedical accumulation, the imaging system sensitivity, and the dose of injected radioactivity. The propagation of errors due to the reconstruction process results in an increase in the noise over that expected for an independent signal, for example, by a factor proportional to the square root of the number of resolution elements (true pixels) across the image. The formula that deals with the general case of emission reconstruction (PET or SPECT) is

$$\% \text{ uncertainty} = \frac{1.2 \times 100(\text{total no. of events})^{3/4}}{(\text{total no. of events})^{1/2}} \quad (16.8)$$

The statistical requirements are closely related to the spatial resolution, as shown in Figure 16.11.

For a given accuracy or a signal-to-noise ratio for a uniform distribution, the ratio of the number of events needed in a high-resolution system to that needed in a low-resolution system is proportional to the  $3/2$  power of the ratio of the number of effective resolution elements in the two systems. Equation 16.8 and Figure 16.11 should be used not with the total pixels in the image but with the effective resolution cells. The number of effective resolution cells is the sum of the occupied resolution elements weighted by the activity within each element. Suppose, however, that the activity is mainly in a few resolution cells (e.g., 100 events per cell) and the remainder of the 10,000 cells have a background of 1 event per cell. The curves of Figure 16.11 would suggest unacceptable statistics; however, in this case, the effective number of resolution cells is below 100. The relevant equation for this situation is

$$\% \text{ uncertainty} = \frac{1.2 \times 100(\text{no. of resolution cells})^{3/4}}{(\text{avg. no. of events per resolution cell in target})^{3/4}} \quad (16.9)$$

The better resolution gives improved results without the requirement for a drastic increase in the number of detected events is that the improved resolution increases contrast. (It is well known that the number of events needed to detect an object is inversely related to the square of the contrast.)

### 17.1 The Electrical Impedance of Tissue

---

The specific conductance (**conductivity**) of human tissues varies from 15.4 mS/cm for cerebrospinal fluid to 0.06 mS/cm for bone. The difference in the value of conductivity is large between different tissues (Table 17.1). Cross-sectional images of the distribution of conductivity, or alternatively specific resistance (**resistivity**), should show good contrast. The aim of electrical impedance tomography (**EIT**) is to produce such images. It has been shown [Kohn and Vogelius, 1984a,b; Sylvester and Uhlmann, 1986] that for reasonable isotropic distributions of conductivity it is possible in principle to reconstruct conductivity images from electrical measurements made on the surface of an object. Electrical impedance tomography (EIT) is the technique of producing these images. In fact, human tissue is not simply conductive. There is evidence that many tissues also demonstrate a capacitive component of current flow and therefore, it is appropriate to speak of the specific admittance (**admittivity**) or specific impedance (**impedivity**) of tissue rather than the conductivity; hence the use of the word impedance in electrical impedance tomography.

### 17.2 Conduction in Human Tissues

---

Tissue consists of cells with conducting contents surrounded by insulating membranes embedded in a conducting medium. Inside and outside the cell wall is conducting fluid. At low frequencies of applied current, the current cannot pass through the membranes, and conduction is through the extracellular space. At high frequencies, current can flow through the membranes, which act as capacitors. A simple

Tissue	Conductivity, mS/cm
Cerebrospinal fluid	15.4
Blood	6.7
Liver	2.8
Skeletal muscle	8.0 (Longitudinal) 0.6 (Transverse)
Cardiac muscle	6.3 (Longitudinal) 2.3 (Transverse)
Neural tissue	1.7
Gray matter	3.5
White matter	1.5
Lung	1.0 (Expiration) 0.4 (Inspiration)
Fat	0.36
Bone	0.06

**FIGURE 17.1** The Cole-Cole model of tissue impedance.

model of bulk tissue impedance based on this structure, which was proposed by Cole and Cole [1941], is shown in Figure 17.1.

Clearly, this model as it stands is too simple, since an actual tissue sample would be better represented as a large network of interconnected modules of this form. However, it has been shown that this model fits experimental data if the values of the components, especially the capacitance, are made a power function of the applied frequency  $\omega$ . An equation which describes the behavior of tissue impedance as a function of frequency reasonably well is

$$Z = Z_{\infty} + \frac{Z_0 - Z_{\infty}}{1 + (j(f/f_c))^\alpha} \tag{17.1}$$

where  $Z_0$  and  $Z_{\infty}$  are the (complex) limiting values of tissue impedance low and high frequency and  $f_c$  is a characteristic frequency. The value of  $\alpha$  allows for the frequency dependency of the components of the model and is tissue dependent. Numerical values for *in vivo* human tissues are not well established.

Making measurements of the real and imaginary components of tissue impedivity over a range of frequencies will allow the components in this model to be extracted. Since it is known that tissue structure alters in disease and that R, S, C are dependent on structure, it should be possible to use such measurements to distinguish different types of tissue and different disease conditions. It is worth noting that although maximum accuracy in the determination of the model components can be obtained if both real and imaginary components are available, in principle, knowledge of the resistive component alone should enable the values to be determined, provided an adequate range of frequencies is used. This can have practical consequences for data collection, since accurate measurement of the capacitive component can prove difficult.

Although on a microscopic scale tissue is almost certainly electrically isotropic, on a macroscopic scale this is not so for some tissues because of their anisotropic physical structure. Muscle tissue is a prime example (see Table 17.1), where the bulk conductivity along the direction of the fibers is significantly higher than across the fibers. Although unique solutions for conductivity are possible for isotropic conductors, it can be shown that for **anisotropic conductors** unique solutions for conductivity do not exist. There are sets of different anisotropic conductivity distributions that give the same surface voltage distributions and which therefore cannot be distinguished by these measurements. It is not yet clear how limiting anisotropy is to electrical impedance tomography. Clearly, if sufficient data could be obtained to resolve down to the microscopic level (this is not possible practically), then tissue becomes isotropic. Moreover, the tissue distribution of conductivity, including anisotropy, often can be modeled as a network of conductors, and it is known that a unique solution will always exist for such a network. In practice, use of some prior knowledge about the anisotropy of tissue may remove the ambiguities of conductivity distribution associated with anisotropy. The degree to which anisotropy might inhibit useful image reconstruction is still an open question.

### 17.3 Determination of the Impedance Distribution

---

The distribution of electrical potential within an isotropic conducting object through which a low-frequency current is flowing is given by

$$\nabla(\sigma \nabla \phi) = 0 \quad (17.2)$$

where  $\phi$  is the potential distribution within the object and  $\sigma$  is the distribution of conductivity (generally admittivity) within the object. If the conductivity is uniform, this reduces to Laplace's equation. Strictly speaking, this equation is only correct for direct current, but for the frequencies of alternating current used in EIT (up to 1 MHz) and the sizes of objects being imaged, it can be assumed that this equation continues to describe the instantaneous distribution of potential within the conducting object. If this equation is solved for a given conductivity distribution and current distribution through the surface of the object, the potential distribution developed on the surface of the object may be determined. The distribution of potential will depend on several things. It will depend on the pattern of current applied and the shape of the object. It will also depend on the internal conductivity of the object, and it is this that needs to be determined. In theory, the current may be applied in a continuous and nonuniform pattern at every point across the surface. In practice, current is applied to an object through electrodes attached to the surface of the object. Theoretically, potential may be measured at every point on the surface of the object. Again, voltage on the surface of the object is measured in practice using electrodes (possibly different from those used to apply current) attached to the surface of the object. There will be a relationship, the forward solution, between an **applied current pattern**  $j_i$ , the conductivity distribution  $\sigma$ , and the surface potential distribution  $\phi_i$  which can be formally represented as

$$\phi_i = R(j_i, \sigma) \quad (17.3)$$

If  $\sigma$  and  $j_i$  are known,  $\phi_i$  can be computed. For one current pattern  $j_i$ , knowledge of  $\phi_i$  is not in general sufficient to uniquely determine  $\sigma$ . However, by applying a complete set of independent current patterns, it becomes possible to obtain sufficient information to determine  $\sigma$ , at least in the isotropic case. This is the inverse solution. In practice, measurements of surface potential or voltage can only be made at a finite number of positions, corresponding to electrodes placed on the surface of the object. This also means that only a finite number of independent current patterns can be applied. For  $N$  electrodes,  $N - 1$  independent current patterns can be defined and  $N(N - 1)/2$  independent measurements made. This latter number determines the limit of image resolution achievable with  $N$  electrodes. In practice, it may not be possible to collect all possible independent measurements. Since only a finite number of current patterns and

measurements is available, the set of equations represented by Equation 17.3 can be rewritten as

$$v = A_c c \quad (17.4)$$

where  $v$  is now a concatenated vector of all voltage values for all current patterns,  $c$  is a vector of conductivity values, representing the conductivity distribution divided into uniform image **pixels**, and  $A_c$  a matrix representing the transformation of this conductivity vector into the voltage vector. Since  $A_c$  depends on the conductivity distribution, this equation is nonlinear. Although formally the preceding equation can be solved for  $c$  by inverting  $A_c$ , the nonlinear nature of this equation means that this cannot be done in a single step. An iterative procedure will therefore be needed to obtain  $c$ .

Examination of the physics of current flow shows that current tends to take the easiest path possible in its passage through the object. If the conductivity at some point is changed, the current path redistributes in such a way that the effects of this change are minimized. The practical effect of this is that it is possible to have fairly large changes in conductivity within the object which only produce relatively small changes in voltage at the surface of the object. The converse of this is that when reconstructing the conductivity distribution, small errors on the measured voltage data, both random and systematic, can translate into large errors in the estimate of the conductivity distribution. This effect forms, and will continue to form, a limit to the quality of reconstructed conductivity images in terms of resolution, accuracy, and sensitivity.

Any measurement of voltage must always be referred to a reference point. Usually this is one of the electrodes, which is given the nominal value of 0 V. The voltage on all other electrodes is determined by measuring the voltage difference between each electrode and the reference electrode. Alternatively, voltage differences may be measured between pairs of electrodes. A common approach is to measure the voltage between adjacent pairs of electrodes (Figure 17.2). Clearly, the measurement scheme affects the form of  $A_c$ . Choice of the pattern of applied currents and the voltage measurement scheme used can affect the accuracy with which images of conductivity can be reconstructed.

Electrical impedance tomography (EIT) is not a mature technology. However, it has been the subject of intensive research over the past few years, and this work is still continuing. Nearly all the research effort has been devoted to exploring the different possible ways of collecting data and producing images of tissue resistivity, with the aim of optimizing image reconstruction in terms of image accuracy, spatial resolution, and sensitivity.

**FIGURE 17.2** Idealized electrode positions around a conducting object with typical drive and measurement electrode pairs indicated.

Very few areas of medical application have been explored in any great depth, although in a number of cases preliminary work has been carried out. Although most current interest is in the use of EIT for medical imaging, there is also some interest in its use in geophysical measurements and some industrial uses. A recent detailed review of the state of Electrical Impedance Tomography is given in Boone et al. [1997].

## 17.3.1 Data Collection

### 17.3.1.1 Basic Requirements

Data are collected by applying a current to the object through electrodes connected to the surface of the object and then making measurements of the voltage on the object surface through the same or other electrodes. Although conceptually simple, technically this can be difficult. Great attention must be paid to the reduction of noise and the elimination of any voltage offsets on the measurements. The currents applied are alternating currents usually in the range 10 kHz to 1 MHz. Since tissue has a complex impedance, the voltage signals will contain in-phase and out-of-phase components. In principle, both of these can be measured. In practice, measurement of the out-of-phase (the capacitive) component is significantly more difficult because of the presence of unwanted (stray) capacitances between various parts of the voltage measurement system, including the leads from the data-collection apparatus to the electrodes. These stray capacitances can lead to appreciable leakage currents, especially at the higher frequencies, which translate into systematic errors on the voltage measurements. The signal measured on an electrode, or between a pair of electrodes, oscillates at the same frequency as the applied current. The magnitude of this signal (usually separated into real and imaginary components) is determined, typically by demodulation and integration. The frequency of the demodulated signal is much less than the frequency of the applied signal, and the effects of stray capacitances on this signal are generally negligible. This realization has led some workers to propose that the signal demodulation and detection system be mounted as close to the electrodes as possible, ideally at the electrode site itself, and some systems have been developed that use this approach, although none with sufficient miniaturization of the electronics to be practical in a clinical setting. This solution is not in itself free of problems, but this approach is likely to be of increasing importance if the frequency range of applied currents is to be extended beyond 1 MHz, necessary if the value of the complex impedance is to be adequately explored as a function of frequency.

Various data-collection schemes have been proposed. Most data are collected from a two-dimensional (2D) configuration of electrodes, either from 2D objects or around the border of a plane normal to the principal axis of a cylindrical (in the general sense) object where that plane intersects the object surface. The simplest data-collection protocol is to apply a current between a pair of electrodes (often an adjacent pair) and measure the voltage difference between other adjacent pairs (see Figure 17.2). Although in principle voltage could be measured on electrodes through which current is simultaneously flowing, the presence of an electrode impedance, generally unknown, between the electrode and the body surface means that the voltage measured is not actually that on the body surface. Various means have been suggested for either measuring the electrode impedance in some way or including it as an unknown in the image-reconstruction process. However, in many systems, measurements from electrodes through which current is flowing are simply ignored. Electrode impedance is generally not considered to be a problem when making voltage measurements on electrodes through which current is not flowing, provided a voltmeter with sufficiently high input impedance is used, although, since the input impedance is always finite, every attempt should be made to keep the electrode impedance as low as possible. Using the same electrode for driving current and making voltage measurements, even at different times in the data collection cycle, means that at some point in the data-collection apparatus wires carrying current and wires carrying voltage signals will be brought close together in a switching system, leading to the possibility of leakage currents. There is a good argument for using separate sets of electrodes for driving and measuring to reduce this problem. Paulson et al. [1992] have also proposed this approach and also have noted that it can aid in the modeling of the forward solution (see Image Reconstruction). Brown et al. [1994] have used this approach in making multi-frequency measurements.

Clearly, the magnitude of the voltage measured will depend on the magnitude of the current applied. If a constant-current drive is used, this must be able to deliver a known current to a variety of input impedances with a stability of better than 0.1%. This is technically demanding. The best approach to this problem is to measure the current being applied, which can easily be done to this accuracy. These measurements are then used to normalize the voltage data.

The current application and data-collection regime will depend on the reconstruction algorithm used. Several EIT systems apply current in a distributed manner, with currents of various magnitudes being applied to several or all of the electrodes. These **optimal currents** (see Image Reconstruction) must be specified accurately, and again, it is technically difficult to ensure that the correct current is applied at each electrode. Although there are significant theoretical advantages to using **distributed current** patterns, the increased technical problems associated with this approach, and the higher noise levels associated with the increase in electronic complexity, may outweigh these advantages.

Although most EIT at present is 2D in the sense given above, it is intrinsically a three-dimensional (3D) imaging procedure, since current cannot be constrained to flow in a plane through a 3D object. 3D data collection does not pose any further problems apart from increased complexity due to the need for more electrodes. Whereas most data-collection systems to date have been based on 16 or 32 electrodes, 3D systems will require four times or more electrodes distributed over the surface of the object if adequate resolution is to be maintained. Technically, this will require “belts” or “vests” of electrodes that can be rapidly applied [McAdams et al., 1994]. Some of these are already available, and the application of an adequate number of electrodes should not prove insuperable provided electrode-mounted electronics are not required. Metherell et al. [1996] describe a three-dimensional data collection system and reconstruction algorithm and note the improved accuracy of three-dimensional images compared to two-dimensional images constructed using data collected from three-dimensional objects.

### 17.3.1.2 Performance of Existing Systems

Several research groups have produced EIT systems for laboratory use [Brown and Seagar, 1987; Rigaud et al., 1990; Smith 1990; Gisser et al., 1991; Jossinet and Trillaud, 1992; Lidgley et al., 1992; Riu et al., 1992; Brown et al., 1994; Cook et al., 1994; Cusick et al., 1994; Zhu et al., 1994] and some clinical trials. The complexity of the systems largely depends on whether current is applied via a pair of electrodes (usually adjacent) or whether through many electrodes simultaneously. The former systems are much simpler in design and construction and can deliver higher signal-to-noise ratios. The Sheffield Mark II system [Smith, 1990] used 16 electrodes and was capable of providing signal-to-noise ratios of up to 17 dB at 25 datasets per second. The average image resolution achievable across the image was 15% of the image diameter. In general, multi-frequency systems have not yet delivered similar performance, but are being continuously improved.

Spatial resolution and noise levels are the most important constraints on possible clinical applications of EIT. As images are formed through a reconstruction process the values of these parameters will depend critically on the quality of the data collected and the reconstruction process used. However practical limitations to the number of electrodes which can be used and the ill-posed nature of the reconstruction problem make it unlikely that high quality images, comparable to other medical imaging modalities, can be produced. The impact of this on diagnostic performance still needs to be evaluated.

## 17.3.2 Image Reconstruction

### 17.3.2.1 Basics of Reconstruction

Although several different approaches to image reconstruction have been tried [Wexler et al., 1985; Yorkey, 1986; Barber and Seagar, 1987, Kim et al., 1987; Hua et al., 1988; Breckon, 1990; Cheny et al., 1990; Zadecoochak et al., 1991; Kotre et al., 1992; Bayford et al., 1994; Morucci et al., 1994], the most accurate approaches are based broadly on the following algorithm. For a given set of current patterns, a forward transform is set up for determining the voltages  $v$  produced from the conductivity distribution  $c$  (Equation 17.4).  $A_c$  is dependent on  $c$ , so it is necessary to assume an initial starting conductivity

distribution  $c_0$ . This is usually taken to be uniform. Using  $A_c$ , the expected voltages  $v_0$  are calculated and compared with the actual measured voltages  $v_m$ . Unless  $c_0$  is correct (which it will not be initially),  $v_0$  and  $v_m$  will differ. It can be shown that an improved estimate of  $c$  is given by

$$\Delta c = (S_c^t S_c)^{-1} S_c^t (v_0 - v_m) \quad (17.5)$$

$$c_1 = c_0 + \Delta c \quad (17.6)$$

where  $S_c$  is the differential of  $A_c$  with respect to  $c$ , the sensitivity matrix and  $S_c^t$  is the transpose of  $S_c$ . The improved value of  $c$  is then used in the next iteration to compute an improved estimate of  $v_m$ , that is,  $v_1$ . This iterative process is continued until some appropriate endpoint is reached. Although convergence is not guaranteed, in practice, convergence to the correct  $c$  in the absence of noise can be expected, provided a good starting value is chosen. Uniform conductivity seems to be a reasonable choice. In the presence of noise on the measurements, iteration is stopped when the difference between  $v$  and  $v_m$  is within the margin of error set by the known noise on the data.

There are some practical difficulties associated with this approach. One is that large changes in  $c$  may only produce small changes in  $v$ , and this will be reflected in the structure of  $S_c$ , making  $S_c^t S_c$  very difficult to invert reliably. Various methods of regularization have been used, with varying degrees of success, to achieve stable inversion of this matrix although the greater the regularization applied the poorer the resolution that can be achieved. A more difficult practical problem is that for convergence to be possible the computed voltages  $v$  must be equal to the measured voltages  $v_m$  when the correct conductivity values are used in the forward calculation. Although in a few idealized cases analytical solutions of the forward problem are possible, in general, numerical solutions must be used. Techniques such as the finite-element method (FEM) have been developed to solve problems of this type numerically. However, the accuracy of these methods has to be carefully examined [Paulson et al., 1992] and, while they are adequate for many applications, may not be adequate for the EIT reconstruction problem, especially in the case of 3D objects. Accuracies of rather better than 1% appear to be required if image artifacts are to be minimized. Consider a situation in which the actual distortion of conductivity is uniform. Then the initial  $v$  should be equal to the  $v_m$  to an accuracy less than the magnitude of the noise. If this is not the case, then the algorithm will alter the conductivity distribution from uniform, which will clearly result in error. While the required accuracies have been approached under ideal conditions, there is only a limited amount of evidence at present to suggest that they can be achieved with data taken from human subjects.

### 17.3.2.2 Optimal Current Patterns

So far little has been said about the form of the current patterns applied to the object except that a set of independent patterns is needed. The simplest current patterns to use are those given by passing current into the object through one electrode and extracting current through a second electrode (a bipolar pattern). This pattern has the virtue of simplicity and ease of application. However, other current patterns are possible. Current can be passed simultaneously through many electrodes, with different amounts passing through each electrode. Indeed, an infinite number of patterns are possible, the only limiting condition being that the magnitude of the current flowing into the conducting object equals the magnitude of the current flowing out of the object. Isaacson [1986] has shown that for any conducting object there is a set of optimal current patterns and has provided an algorithm to compute them even if the conductivity distribution is initially unknown. Isaacson showed that by using optimal patterns, significant improvements in sensitivity could be obtained compared with simpler two-electrode current patterns. However, the additional computation and hardware required to use optimal current patterns compared with fixed, nonoptimal patterns is considerable.

Use of suboptimal patterns close to optimum also will produce significant gains. In general, the optimal patterns are very different from the patterns produced in the simple two-electrode case. The optimal patterns are often cosine-like patterns of current amplitude distributed around the object boundary

rather than being localized at a pair of points, as in the two-electrode case. Since the currents are passed simultaneously through many electrodes, it is tempting to try and use the same electrodes for voltage measurements. This produces two problems. As noted above, measurement of voltage on an electrode through which an electric current is passing is compromised by the presence of electrode resistance, which causes a generally unknown voltage drop across the electrode, whereas voltage can be accurately measured on an electrode through which current is not flowing using a voltmeter of high input impedance. In addition, it has proved difficult to model current flow around an electrode through which current is flowing with sufficient accuracy to allow the reliable calculation of voltage on that electrode, which is needed for accurate reconstruction. It seems that separate electrodes should be used for voltage measurements with distributed current systems.

Theoretically, distributed (near-) optimal current systems have some advantages. As each of the optimal current patterns is applied, it is possible to determine if the voltage patterns produced contain any useful information or if they are simply noise. Since the patterns can be generated and applied in order of decreasing significance, it is possible to terminate application of further current patterns when no further information can be obtained. A consequence of this is that SNRs can be maximized for a given total data-collection time. With **bipolar current patterns** this option is not available. All patterns must be applied. Provided the SNR in the data is sufficiently good and only a limited number of electrodes are used, this may not be too important, and the extra effort involved in generating the optimal or near-optimal patterns may not be justified. However, as the number of electrodes is increased, the use of optimal patterns becomes more significant. It also has been suggested that the distributed nature of the optimal patterns makes the forward problem less sensitive to modeling errors. Although there is currently no firm evidence for this, this seems a reasonable assertion.

### 17.3.2.3 Three-Dimensional Imaging

Most published work so far on image reconstruction has concentrated on solving the 2D problem. However, real medical objects, that is, patients, are three-dimensional. Theoretically, as the dimensionality of the object increases, reconstruction should become better conditioned. However, unlike 3D x-ray images, which can be constructed from a set of independent 2D images, EIT data from 3D objects cannot be so decomposed and data from over the whole surface of the object is required for 3D reconstruction. The principles of reconstruction in 3D are identical to the 2D situation although practically the problem is quite formidable, principally because of the need to solve the forward problem in three dimensions. Some early work on 3D imaging was presented by Goble and Isaacson [1990]. More recently Metherall et al. [1996] have shown images using data collected from human subjects.

### 17.3.2.4 Single-Step Reconstruction

The complete reconstruction problem is nonlinear and requires iteration. However, each step in the iterative process is linear. Images reconstructed using only the first step of iteration effectively treat image formation as a linear process, an assumption approximately justified for small changes in conductivity from uniform. In the case the functions  $A_c$  and  $S_c$  often can be precomputed with reasonable accuracy because they usually are computed for the case of uniform conductivity. Although the solution cannot be correct, since the nonlinearity is not taken into account, it may be useful, and first-step linear approximations have gained some popularity. Cheney et al. [1990] have published some results from a first-step process using optimal currents. Most, if not all, of the clinical images produced to date have used a single-step reconstruction algorithm [Barber and Seagar, 1987; Barber and Brown, 1990]. Although this algorithm uses very nonoptimal current patterns, this has not so far been a limitation because of the high quality of data collected and the limited number of electrodes used (16). With larger numbers of electrodes, this conclusion may need to be revised.

### 17.3.2.5 Differential Imaging

Ideally, the aim of EIT is to reconstruct images of the absolute distribution of conductivity (or admittivity). These images are known as absolute (or static) images. However, this requires that the forward problem

can be solved to an high degree of accuracy, and this can be difficult. The magnitude of the voltage signal measured on an electrode or between electrodes will depend on the body shape, the electrode shape and position, and the internal conductivity distribution. The signal magnitude is in fact dominated by the first two effects rather than by conductivity. However, if a change in conductivity occurs within the object, then it can often be assumed that the change in surface voltage is dominated by this conductivity change. In differential (or dynamic) imaging, the aim is to image changes in conductivity rather than absolute values. If the voltage difference between a pair of (usually adjacent) electrodes before a conductivity change occurs is  $g_1$  and the value after change occurs is  $g_2$ , then a normalized data value is defined as

$$\Delta g_n = 2 \frac{g_1 - g_2}{g_1 + g_2} = \frac{\Delta g}{g_{\text{mean}}} \quad (17.7)$$

Many of the effects of body shape (including interpreting the data as coming from a 2D object when in fact it is from a 3D object) and electrode placing at least partially cancel out in this definition. The values of the normalized data are determined largely by the conductivity changes. It can be argued that the relationship between the (normalized) changes in conductivity  $\Delta c_n$  and the normalized changes in boundary data  $\Delta g_n$  is given by

$$\Delta g_n = F \Delta c_n \quad (17.8)$$

where  $F$  is a sensitivity matrix which it can be shown is much less sensitive to object shape and electrode positions than the sensitivity matrix of Equation 17.5. Although images produced using this algorithm are not completely free of artifact that is the only algorithm which has reliably produced images using data taken from human subjects. Metherall et al. [1996] used a version of this algorithm for 3D imaging and Brown et al. [1994] for multi-frequency imaging, in this case imaging changes in conductivity with frequency. The principle disadvantage of this algorithm is that it can only image changes in conductivity, which must be either natural or induced. Figure 17.3 shows a typical differential image. This represents the changes in the conductivity of the lungs between expiration and inspiration.

**FIGURE 17.3** A differential conductivity image representing the changes in conductivity in going from maximum inspiration (breathing in) to maximum expiration (breathing out). Increasing blackness represents increasing conductivity.

### 17.3.3 Multifrequency Measurements

Differential algorithms can only image changes in conductivity. Absolute distributions of conductivity cannot be produced using these methods. In addition, any gross movement of the electrodes, either because they have to be removed and replaced or even because of significant patient movement, make the use of this technique difficult for long-term measurements of changes. As an alternative to changes in time, differential algorithms can image changes in conductivity with frequency. Brown et al. [1994] have shown that if measurements are made over a range of frequencies and differential images produced using data from the lowest frequency and the other frequencies in turn, these images can be used to compute parametric images representing the distribution of combinations of the circuit values in Figure 17.1. For example, images representing the ratio of S to R, a measure of the ratio of intracellular to extracellular volume, can be produced, as well as images of  $f_o = 1/2p(RC + SC)$ , the tissue characteristic frequency. Although not images of the absolute distribution of conductivity, they are images of absolute tissue properties. Since these properties are related to tissue structure, they should produce images with useful contrast. Data sufficient to reconstruct an image can be collected in a time short enough to preclude significant patient movement, which means these images are robust against movement artifacts. Changes of these parameters with time can still be observed.

## 17.4 Areas of Clinical Application

---

There is no doubt that the clinical strengths of EIT relate to its ability to be considered as a functional imaging modality that carries no hazard and can therefore be used for monitoring purposes. The best spatial resolution that might become available will still be much worse than anatomic imaging methods such as magnetic resonance imaging and x-ray computed tomography. However, EIT is able to image small changes in tissue conductivity such as those associated with blood perfusion, lung ventilation, and fluid shifts. Clinical applications seek to take advantage of the ability of EIT to follow rapid changes in physiologic function.

There are several areas in clinical medicine where electrical impedance tomography might provide advantages over existing techniques. These have been received elsewhere [Brown et al., 1985; Dawids, 1987; Holder and Brown, 1990; Boone et al., 1997].

### 17.4.1 Possible Biomedical Applications

#### 17.4.1.1 Gastrointestinal System

A priori, it seems likely that EIT could be applied usefully to measurement of motor activity in the gut. Electrodes can be applied with ease around the abdomen, and there are no large bony structures likely to seriously violate the assumption of constant initial conductivity. During motor activity, such as gastric emptying or peristalsis, there are relatively large movements of the conducting fluids within the bowel. The quantity of interest is the timing of activity, for example, the rate at which the stomach empties, and the absolute impedance change and its exact location in space area of secondary importance. The principal limitations of EIT of poor spatial resolution and amplitude measurement are largely circumvented in this application [Avill et al., 1987]. There has also been some interest in the measurement of other aspects of gastro-intestinal function such as oesophageal activity [Erol et al., 1995].

#### 17.4.1.2 Respiratory System

Lung pathology can be imaged by conventional radiography, x-ray computed tomography, or magnetic resonance imaging, but there are clinical situations where it would be desirable to have a portable means of imaging regional lung ventilation which could, if necessary, generate repeated images over time. Validation studies have shown that overall ventilation can be measured with good accuracy [Harris et al., 1988]. More recent work [Hampshire et al., 1995] suggests that multifrequency measurements may be useful in the diagnosis of some lung disorders.

### 17.4.1.3 EIT Imaging of Changes in Blood Volume

The conductivity of blood is about 6.7 mS/cm, which is approximately three times that of most intrathoracic tissues. It therefore seems possible that EIT images related to blood flow could be accomplished. The imaged quantity will be the change in conductivity due to replacement of tissue by blood (or vice versa) as a result of the pulsatile flow through the thorax. This may be relatively large in the cardiac ventricles but will be smaller in the peripheral lung fields.

The most interesting possibility is that of detecting pulmonary embolus (PE). If a blood clot is present in the lung, the lung beyond the clot will not be perfused, and under favorable circumstances, this may be visualized using a gated blood volume image of the lung. In combination with a ventilation image, which should show normal ventilation in this region, pulmonary embolism could be diagnosed. Some data [Leathard et al., 1994] indicate that PE can be visualized in human subjects. Although more sensitive methods already exist for detecting PE, the noninvasiveness and bedside availability of EIT mean that treatment of the patient could be monitored over the period following the occurrence of the embolism, an important aim, since the use of anticoagulants, the principal treatment for PE, needs to be minimized in postoperative patients, a common class of patients presenting with this complication.

## 17.5 Summary and Future Developments

---

Electrical Impedance Tomography is still an emerging technology. In its development, several novel and difficult measurement and image-reconstruction problems have had to be addressed. Most of these have been satisfactorily solved. The current generation of EIT imaging systems are multifrequency, with some capable of 3D imaging. These should be capable of greater quantitative accuracy and be less prone to image artifact and are likely to find a practical role in clinical diagnosis. Although there are still many technical problems to be answered and many clinical applications to be addressed, the technology may be close to coming of age.

### Defining Terms

**Absolute imaging:** Imaging the actual distribution of conductivity.

**Admittivity:** The specific admittance of an electrically conducting material. For simple biomedical materials such as saline with no reactive component of resistance, this is, the same as conductivity.

**Anisotropic conductor:** A material in which the conductivity is dependent on the direction in which it is measured through the material.

**Applied current pattern:** In EIT, the electric current is applied to the surface of the conducting object via electrodes placed on the surface of the object. The spatial distribution of current flow through the surface of the object is the applied current pattern.

**Bipolar current pattern:** A current pattern applied between a single pair of electrodes.

**Conductivity:** The specific conductance of an electrically conducting material. The inverse of resistivity.

**Differential imaging:** An EIT imaging technique that specifically images changes in conductivity.

**Distributed current:** A current pattern applied through more than two electrodes.

**Dynamic imaging:** The same as differential imaging.

**EIT:** Electrical impedance tomography.

**Forward transform or problem or solution:** The operation, real or computational, that maps or transforms the conductivity distribution to surface voltages.

**Impedivity:** The specific impedance of an electrically conducting material. The inverse of admittivity. For simple biomedical materials such as saline with no reactive component of resistance, this is the same as resistivity.

**Inverse transform or problem or solution:** The computational operation that maps voltage measurements on the surface of the object to the conductivity distribution.

- Optimal current:** One of a set of a current patterns computed for a particular conductivity distribution that produce data with maximum possible SNR.
- Pixel:** The conductivity distribution is usually represented as a set of connected piecewise uniform patches. Each of these patches is a pixel. The pixel may take any shape, but square or triangular shapes are most common.
- Resistivity:** The specific electrical resistance of an electrical conducting material. The inverse of conductivity.
- Static imaging:** The same as absolute imaging.

Virtual reality (VR) is the term commonly used to describe a novel human–computer interface that enables users to interact with computers in a radically different way. VR consists of a computer-generated, multi-dimensional environment and interface tools that allow users to:

1. Immerse themselves in the environment
2. Navigate within the environment
3. Interact with objects and other inhabitants in the environment

The experience of entering this environment — this computer-generated virtual world — is compelling. To enter, the user usually dons a helmet containing a head-mounted display (HMD) that incorporates a sensor to track the wearer’s movement and location. The user may also wear sensor-clad clothing that likewise tracks movement and location. The sensors communicate position and location data to a computer, which updates the image of the virtual world accordingly. By employing this garb, the user “breaks through” the computer screen and becomes completely immersed in this multi-dimensional world. Thus immersed, one can walk through a virtual house, drive a virtual car, or run a marathon in a park still

under design. Recent advances in computer processor speed and graphics make it possible for even desktop computers to create highly realistic environments. The practical applications are far reaching. Today, using VR, architects design office buildings, NASA controls robots at remote locations, and physicians plan and practice difficult operations.

Virtual reality is quickly finding wide acceptance in the medical community as researchers and clinicians alike become aware of its potential benefits. Several pioneer research groups have already demonstrated improved clinical performance using VR imaging, planning, and control techniques.

## 18.1 Overview of Virtual Reality Technology

The term “Virtual Reality” describes the experience of interacting with data from within the computer-generated data set. The computer-generated data set may be completely synthetic or remotely sensed, such as x-ray, magnetic resonance imaging (MRI), positron emission tomography (PET), etc., images. Interaction with the data is natural and intuitive and occurs from a first-person perspective. From a system perspective, VR technology can be segmented as shown in Figure 18.1. The computer-generated environment, or virtual world content consists of a 3D graphic model, typically implemented as a spatially organized, object-oriented database; each object in the database represents an object in the virtual world.

A separate modeling program is used to create the individual objects for the virtual world. For greater realism, texture maps are used to create visual surface detail.

The data set is manipulated using a real-time dynamics generator that allows objects to be moved within the world according to natural laws such as gravity and inertia, or according to other variables such as spring-rate and flexibility that are specified for each particular experience by application-specific programming. The dynamics generator also tracks the position and orientation of the user’s head and hand using input peripherals such as a head tracker and DataGlove. Powerful renderers are applied to present 3D images and 3D spatialized sound in real time to the observer.

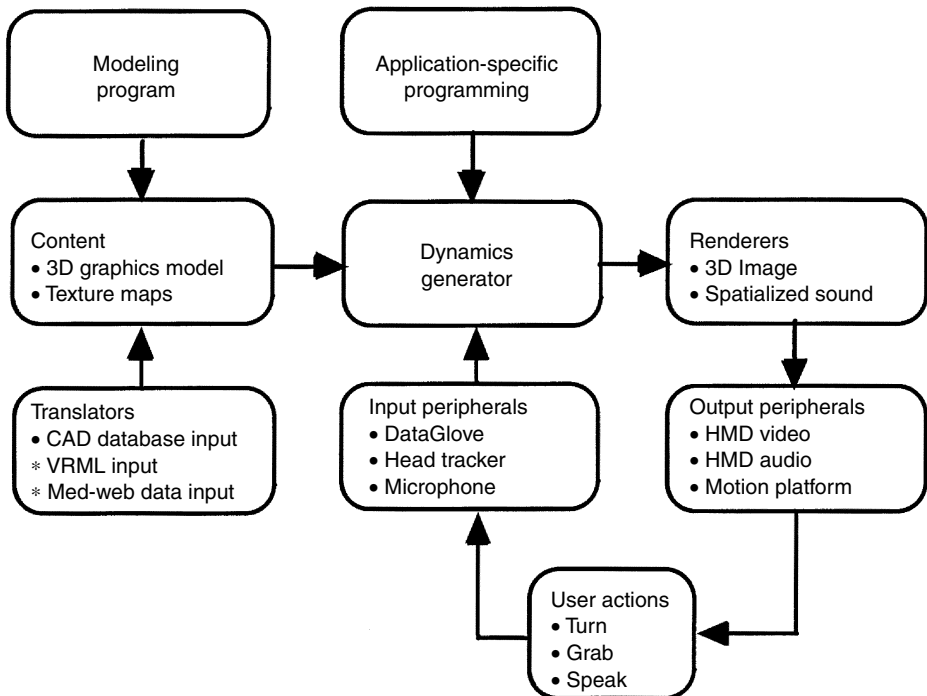

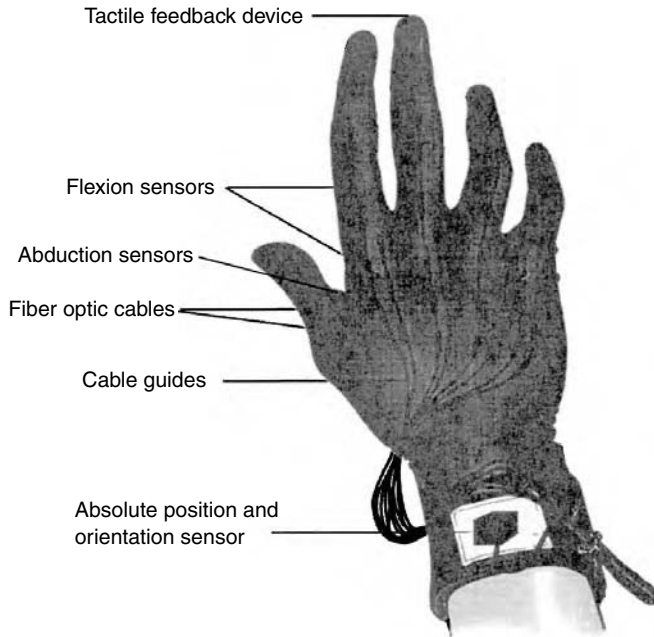

FIGURE 18.1 A complete VR system.

**FIGURE 18.2** The DataGlove™, a VR control device.

The common method of working with a computer (the mouse/keyboard/monitor paradigm), based as it is, on a two-dimensional desk-top metaphor, is inappropriate for the multi-dimensional virtual world. Therefore, one long-term challenge for VR developers has been to replace the conventional computer interface with one that is more natural, intuitive, and allows the computer — not the user — to carry a greater proportion of the interface burden. Not surprisingly, this search for a more practical multi-dimensional metaphor for interacting with computers and computer-generated artificial environments has spawned the development of a new generation of computer interface hardware. Ideally, the interface hardware should consist of two components (1) sensors for controlling the virtual world and (2) effectors for providing feedback to the user. To date, three new computer-interface mechanisms, not all of which manifest the ideal sensor/effector duality, have evolved: Instrumented Clothing, the Head Mounted Display (HMD), and 3D Sound Systems.

### 18.1.1 Instrumented Clothing

The DataGlove™ and DataSuit™ use dramatic new methods to measure human motion dynamically in real time. The clothing is instrumented with sensors that track the full range of motion of specific activities of the person wearing the Glove or Suit, for example as the wearer bends, moves, grasps, or waves.

The DataGlove is a thin lycra glove with bend-sensors running along its dorsal surface. When the joints of the hand bend, the sensors bend and the angular movement is recorded by the sensors. These recordings are digitized and forwarded to the computer, which calculates the angle at which each joint is bent. On screen, an image of the hand moves in real time, reflecting the movements of the hand in the DataGlove and immediately replicating even the most subtle actions.

The DataGlove is often used in conjunction with an absolute position and orientation sensor that allows the computer to determine the three-space coordinates, as well as the orientation of the hand and fingers. A similar sensor can be used with the DataSuit and is nearly always used with an HMD.

The DataSuit is a customized body suit fitted with the same sophisticated bend-sensors found in the DataGlove. While the DataGlove is currently in production as both a VR interface and as a data-collection instrument, the DataSuit is available only as a custom device. As noted, DataGlove and DataSuit are

**FIGURE 18.3** VR-based rehabilitation workstation.

utilized as general purpose computer interface devices for VR. There are several potential applications of this new technology for clinical and therapeutic medicine.

### 18.1.2 Head-Mounted Display (HMD)

The best-known sensor/effector system in VR is a head-mounted display (HMD). It supports first-person immersion by generating an image for each eye, which, in some HMDs, may provide stereoscopic vision. Most lower cost HMDs (\$6000 range) use LCD displays; others use small cathode ray tubes (CRTs). The more expensive HMDs (\$60,000 and up) use optical fibers to pipe the images from remotely mounted CRTs. An HMD requires a position/orientation sensor in addition to the visual display. Some displays, for example the binocular omni orientational monitors (BOOM) System [Bolas, 1994], may be head-mounted or may be used as a remote window into a virtual world.

### 18.1.3 3D Spatialized Sound

The impression of immersion within a virtual environment is greatly enhanced by inclusion of 3D spatialized sound [Durlach, 1994; Hendrix and Barfield, 1996]. Stereo-pan effects alone are inadequate since they tend to sound as if they are originating inside the head. Research into 3D audio has shown the importance of modeling the head and pinna and using this model as part of the 3D sound generation. A head related transfer function (HRTF) can be used to generate the proper acoustics [Begault and Wenzel, 1992; Wenzel, 1994]. A number of problems remain, such as the “cone of confusion” wherein sounds behind the head are perceived to be in front of the head [Wenzel, 1992].

### 18.1.4 Other VR Interface Technology

A sense of motion can be generated in a VR system by a motion platform. These have been used in flight simulators to provide cues that the mind integrates with visual and spatialized sound cues to generate perception of velocity and acceleration.

**FIGURE 18.4** DataSuit™ for ergonomic and sports medicine applications.

Haptics is the science of touch. Haptic interfaces generate perception of touch and resistance in VR. Most systems to date have focused on providing force feedback to enable users to sense the inertial qualities of virtual objects, and/or kinesthetic feedback to specify the location of a virtual object in the world [Salisbury and Srinivasan, 1996, 1997]. A few prototype systems exist that generate tactile stimulation, which allow users to feel the surface qualities of virtual objects [Minsky and Lederman, 1996]. Many of the haptic systems developed thus far consist of exo-skeletons that provide position sensing as well as active force application [Burdea et al., 1992].

Some preliminary work has been conducted on generating the sense of temperature in VR. Small electrical heat pumps have been developed that produce sensations of heat and cold as part of the simulated environment [Caldwell and Gosney, 1993; Ino et al., 1993].

Olfaction is another sense that provides important cues in the real world. Consider, for example, a surgeon or dentist examining a patient for a potential bacterial infection. Inflammation and swelling may be present, but a major deciding factor is the odor of the lesion. Very early in the history of virtual reality, Mort Heilig patented his Sensorama Simulator, which incorporated olfactory, as well as visual, auditory, and motion cues (U.S. Patent 3850870, 1961). Recently, another pioneer of virtual reality, Myron Kreuger [1994, 1995a,b], has been developing virtual olfaction systems for use in medical training applications. The addition of virtual olfactory cues to medical training systems should greatly enhance both the realism and effectiveness of training.

## 18.2 VR Application Examples

---

Virtual reality had been researched for years in government laboratories and universities, but because of the enormous computing power demands and associated high costs, applications have been slow to migrate from the research world to other areas. Continual improvements in the price/performance ratio of graphic computer systems, however, have made VR technology more affordable and, thus, used more commonly in a wider range of application areas. In fact, there is even a strong “Garage VR” movement — groups of interested parties sharing information on how to build extremely low-cost VR systems using inexpensive off-the-shelf components [Jacobs, 1994]. These home-made systems are often inefficient, uncomfortable to use (sometimes painful), and slow, but they exist as a strong testament to a fervent interest in VR technology.

### 18.2.1 VR Applications

Applications today are diverse and represent dramatic improvements over conventional visualization and planning techniques:

*Public entertainment:* VR made its first major inroads in the area of public entertainment, with ventures ranging from shopping mall game simulators to low-cost VR games for the home. Major growth continues in home VR systems, partially as a result of 3D games on the Internet.

*Computer-aided design:* Using VR to create “virtual prototypes” in software allows engineers to test potential products in the design phase, even collaboratively over computer networks, without investing time or money for conventional hard models. All of the major automobile manufacturers and many aircraft manufacturers rely heavily on virtual prototyping.

*Military:* With VR, the military’s solitary cab-based systems have evolved to extensive networked simulations involving a variety of equipment and situations. There is an apocryphal story that General Norman Schwarzkopf was selected to lead the Desert Storm operation on the basis of his extensive experience with simulations of the Middle East battle arena.

*Architecture/construction:* VR allows architects and engineers and their clients to “walk through” structural blueprints. Designs may be understood more clearly by clients who often have difficulty comprehending them even with conventional cardboard models. Atlanta, Georgia credits its VR model for winning it the site of the 1996 Olympics, while San Diego is using a VR model of a planned convention center addition to compete for the next convention of the Republican Party.

*Data visualization:* By allowing navigation through an abstract “world” of data, VR helps users rapidly visualize relationships within complex, multi-dimensional data structures. This is particularly important in financial-market data, where VR supports faster decision-making. VR is commonly associated with exotic “fully immersive applications” because of the overdramatized media coverage on helmets, body suits, entertainment simulators, and the like. Equally important are the “Window into World” applications where the user or operator is allowed to interact effectively with “virtual” data, either locally or remotely.

## 18.3 Current Status of Virtual Reality Technology

---

The commercial market for VR, while taking advantage of advances in VR technology at large, is nonetheless contending with the lack of integrated systems and the frequent turnover of equipment suppliers. Over the last few years, VR users in academia and industry have developed different strategies for circumventing these problems. In academic settings, researchers buy peripherals and software from separate companies and configure their own systems to maintain the greatest application versatility. In industry, however, expensive, state-of-the-art VR systems are vertically integrated to address problems peculiar to the industry.

Each solution is either too costly or too risky for most medical organizations. What is required is a VR system tailored to the needs of the medical community. Unfortunately, few companies offer integrated systems that are applicable to the VR medical market. This situation is likely to change in the next few years as VR-integration companies develop to fill this void.

At the same time, the nature of the commercial VR medical market is changing as the price of high-performance graphics systems continues to decline. High-resolution graphics monitors are becoming more cost-effective even for markets that rely solely on desktop computers. Technical advances are also occurring in networking, visual photo-realism, tracker latency through predictive algorithms, and variable-resolution image generators. Improved database access methods are underway. Hardware advances, such as eye gear that provide an increased field of view with high-resolution, untethered VR systems and inexpensive intuitive input devices, for example, DataGloves, have lagged behind advances in computational, communications, and display capabilities.

FIGURE 18.5 VR system used as a disability solution.

## 18.4 Overview of Medical Applications of Virtual Reality Technology

---

Within the medical community, the first wave of VR development efforts have evolved into six key categories:

1. Surgical training and surgical planning
2. Medical education, modeling, and nonsurgical training
3. Anatomical imaging and medical image fusion
4. Ergonomics, rehabilitation, and disabilities
5. Telesurgery and telemedicine
6. Behavioral evaluation and intervention

The potential of VR through education and information dissemination indicates there will be few areas of medicine not taking advantage of this improved computer interface. However, the latent potential of VR lies in its capacity to be used to manipulate and combine heterogeneous multi-dimensional data sets from many sources, for example, MRI, PET, and x-ray images. This feature is most significant and continues to transform the traditional applications environment.

### 18.4.1 Surgical Training and Surgical Planning

Various projects are underway to utilize VR and imaging technology to plan, simulate, and customize invasive (as well as minimally invasive) surgical procedures. One example of a VR surgical-planning and training system is the computer-based workstation developed by Ciné-Med of Woodbury, Connecticut [McGovern, 1994]. The goal was to develop a realistic, interactive training workstation that helps surgeons make a more seamless transition from surgical simulation to the actual surgical event.

Ciné-Med focused on television-controlled endosurgical procedures because of the intensive training required for endosurgery and the adaptability of endosurgery to high quality imaging. Surgeons can

gain clinical expertise by training on this highly realistic and functional surgical simulator. Ciné-Med's computer environment includes life-like virtual organs that react much like their real counterparts, and sophisticated details such as the actual surgical instruments that provide system input/output (I/O). To further enhance training, the simulator allows the instructor to adapt clinical instruction to advance the technical expertise of learners. Surgical anomalies and emergency situations can be replicated to allow practicing surgeons to experiment and gain technical expertise on a wide range of surgical problems using the computer model before using an animal model. Since the steps of the procedure can be repeated and replayed at a later time, the learning environment surpasses other skills-training modalities.

The current prototype simulates the environment of laparoscopic cholecystectomy for use as a surgical training device. Development began with the creation of an accurate anatomic landscape, including the liver, the gallbladder, and related structures. Appropriate surgical instruments are used for the system I/O and inserted into a fiberglass replica of a human torso. Four surgical incisional ports are assigned for three scissors grip instruments and camera zoom control. The instruments, retrofitted with switching devices, read and relay the opening and closing of the tips, with position trackers located within the simulator. The virtual surgical instruments are graphically generated on a display monitor where they interact with fully textural, anatomically correct, three-dimensional virtual organs. The organs are created as independent objects and conform to object-oriented programming.

To replicate physical properties, each virtual organ must be assigned appropriate values to dictate its reaction when contacted by a virtual surgical instrument. Collision algorithms are established to define when the virtual organ is touched by a virtual surgical instrument. Additionally, with the creation of spontaneous objects resulting from the dissection of a virtual organ, each new object is calculated to have independent physical properties using artificial intelligence (AI) subroutines. Collision algorithms drive the programmed creation of spontaneous objects.

To reproduce the patient's physiological reactions during the surgical procedure, the simulation employs an expert system. This software sub-system generates patient reactions and probable outcomes derived from surgical stimuli, for example, bleeding control, heart rate failure, and, in the extreme, a death outcome. The acceptable value ranges of these factors are programmed to be constantly updated by the expert system while important data is displayed on the monitor.

Three-dimensional graphical representation of a patient's anatomy is a challenge for accurate surgical planning. Technological progress has been seen in the visualization of bone, brain, and soft tissue. Heretofore, three-dimensional modeling of soft tissue has been difficult and often inaccurate owing to the intricacies of the internal organ, its vasculature, ducts, volume, and connective tissues.

As an extension of this surgical simulator, a functional surgical planning device using VR technology is under development that will enable surgeons to operate on an actual patient, in virtual reality, prior to the actual operation. With the advent of technological advances in anatomic imaging, the parallel development of a surgical planning device incorporating real-time interaction with computer graphics that mimic a patient's anatomy is possible. Identification of anatomical structures to be modeled constitutes the initial phase for development of the surgical planning device. A spiral CAT scanning device records multiple slices of the anatomy during a single breath inhalation by the patient. Pin-registered layers of the anatomy are thus provided for the computer to read.

Individual anatomical structures are defined at the scan level according to gray scale. Once the anatomical structures are identified and labeled, the scans are stacked and connected. The result is a volumetric polygonal model of the patient's actual anatomy. A polygon-reduction program is initiated to create a wire frame that can be successfully texture-mapped and interacted with in real time. As each slice of the CAT scan is stacked and linked together, the result is a fully volumetric, graphic representation of the human anatomy. Since the model, at this point, is unmanageable by the graphics workstation because of the volume polygons, a polygon-reduction program is initiated to eliminate excessive polygons.

Key to the planning device is development of a user-friendly software program that will allow the radiologist to define anatomical structures, incorporate them into graphical representations, and assign physiological parameters to the anatomy. Surgeons will then be able to diagnose, plan, and prescribe appropriate therapy to their patients using a trial run of a computerized simulation.

Several VR-based systems currently under development allow real-time tracking of surgical instrumentation and simultaneous display and manipulation of three-dimensional anatomy corresponding to the simulated procedure [Hon, 1994; McGovern, 1994; Edmond et al., 1997]. With this design surgeons can practice procedures and experience the possible complications and variations in anatomy encountered during surgery. Ranging from advanced imaging technologies for endoscopic surgery to routine hip replacements, these new developments will have a tremendous impact on improving surgical morbidity and mortality. According to Merrill [1993, 1994], studies show that doctors are more likely to make errors performing their first few to several dozen diagnostic and therapeutic surgical procedures. Merrill claims that operative risk could be substantially reduced by the development of a simulator that allows transference of skills from the simulation to the actual point of patient contact.

A preliminary test of Merrill's claim was achieved by Taffinder and colleagues [1998]. Following the observations by McDougall et al. [1996] that 2D representations of anatomic imagery are insufficient to develop the eye-hand coordination of surgeons, Taffinder et al. conducted randomized, controlled studies of psychomotor skills developed either through the use of the Minimally Invasive Surgical Trainer-Virtual Reality (MIST-VR) Laparoscopic Simulator or through a standard laparoscopic-surgery training course. They used the MIST-VR Laparoscopic Simulator to compare the psychomotor skills of experienced surgeons, surgeon trainees, and nonsurgeons. When task speed and the number of correctional movements were compared across subjects, experienced surgeons surpassed trainees and nonsurgeons. Taffinder and colleagues also noted that among trainees, training on the VR system improved efficiency and reduced errors, but did not increase the speed of the laparoscopic procedures.

To increase the realism of medical simulators, software tools have been developed to create "virtual tissues" that reflect the physical characteristics of physiological tissues. This technology operates in real-time using three-dimensional graphics, on a high speed computer platform. Recent advances in creating virtual tissues have occurred as force feedback is incorporated into more VR systems and the computational overhead of finite-element analysis is reduced [see, e.g., Grabowski, 1998; McNerney and Terzopoulos, 1996]. Bro-Nielsen and Cotin [1996] have been developing tissue models that incorporate appropriate real-time volumetric deformation in response to applied forces. Their goal was to provide surgeons with the same "hands-on" feel in VR that they experience in actual surgery. They used mass-spring systems [Bro-Nielsen, 1997] to simplify finite-element analysis, significantly reduced computational overhead, and thereby achieving near-real-time performance. While advancing the state of the art considerably toward the real-time, hands-on objective, much more work remains to be done.

In another study of the effectiveness of force-feedback in surgical simulations, Baur et al. [1998] reported on the use of VIRGY, a VR endoscopic surgery simulator. VIRGY provides both visual and force feedback to the user, through the use of the Pantoscope [Baumann, 1996]. Because the Pantoscope is a remote-center-of-motion force-reflecting system, Baur et al. were able to hide the system beneath the skin of the endoscope mannequin. Force reflection of tissue interactions, including probing and cutting, was controlled by nearest neighbor propagation of look-up table values to circumvent the computational overhead inherent in finite element analysis. Surgeons were asked to assess the tissue feel achieved through this simulation.

Evaluation of another surgical simulator system was carried out by Weghorst et al. [1998]. This evaluation involved the use of the Madigan Endoscopic Sinus Surgery (ESS) Simulator (see Edmond et al. [1997] for a full description), developed jointly by the U.S. Army, Lockheed-Martin, and the Human Interface Technology Laboratory at the University of Washington. The ESS Simulator, which was designed to train otolaryngologists to perform paranasal endoscopic procedures, incorporates 3D models of the naso-pharyngeal anatomy derived from the National Library of Medicine's Virtual Human Data Base. It employs two 6-DOF force-reflecting instruments developed by the Immersion Corporation to simulate the endoscope and 11 surgical instruments used in paranasal surgery.

Weghorst and colleagues pitted three groups of subjects against each other in a test of the effectiveness of the ESS Simulator: non-MDs, non-ENT MDs, and ENTs with various levels of experience. Training aids, in the form of circular hoops projected onto the simulated nasal anatomy, identified the desired endoscope trajectory; targets identified anatomical injection sites; and text labels identified anatomical

landmarks. Successive approximations to the actual task involved training first on an abstract, geometric model of the nasal anatomy with superimposed training aids (Level 1); next on real nasal anatomy with superimposed training aids (Level 2); and finally, on real nasal anatomy without training aids (Level 3).

Results of the evaluation indicated that, in general, ENTs performed better than non-ENTs on Level 1 and 2 tasks, and that among the ENTs, those with more ESS experience scored higher than those who had performed fewer ESS procedures. The researchers also found that deviations from the optimum endoscope path differentiated ENT and non-ENT subjects. In post-training questionnaires, ENTs rated the realism of the simulation as high and confirmed the validity and usefulness of training on the ESS Simulator.

While the ESS Simulator described above requires a 200 MHz Pentium PC and a 4-CPU SGI Oxyx with Reality Engine 2 graphics to synthesize the virtual nasal cavity, a current trend in surgical simulation is toward lower-end simulation platforms. As computational power of PCs continues to escalate, simulations are increasingly being ported to or developed on relatively inexpensive computers. Tseng et al. [1998] used an Intel-based PC as the basis of their laparoscopic surgery simulator. This device incorporates a 5-DOF force-reflecting effector, a monitor for viewing the end-effector, and a speech-recognition system for changing viewpoint. The system detects collisions between the end effector and virtual tissues, and is capable of producing tissue deformation through one of several models including a finite element model, a displacement model, or a transmission line model. Computational power is provided by dual Pentium Pro 200 MHz CPUs and a Realizm Graphics Accelerator Board.

### 18.4.2 Medical Education, Modeling, and Nonsurgical Training

Researchers at the University of California — San Diego are exploring the value of hybridizing elements of VR, multimedia (MM), and communications technologies into a unified educational paradigm [Hoffman, 1994; Hoffman et al., 1995; Hoffman et al., 1997]. The goal is to develop powerful tools that extend the flexibility and effectiveness of medical teaching and promote lifelong learning. To this end, they have undertaken a multi-year initiative, named the “VR-MM Synthesis Project.” Based on instructional design and user-need (rather than technology per se), they have planned a linked 3-computer array representing the Data Communications Gateway, the Electronic Medical Record System, and the Simulation Environment. This system supports medical students, surgical residents, and clinical faculty running applications ranging from full surgical simulation to basic anatomical exploration and review, all via a common interface. The plan also supports integration of learning and telecommunications resources (such as interactive MM libraries, online textbooks, databases of medical literature, decision support systems, electronic mail, and access to electronic medical records).

The first application brought to fruition in the VR-MM Synthesis Project is an anatomical instructional-aid system called Anatomic VisualizeR [Hoffman et al., 1997] that uses anatomical models derived from the Visible Human Project of the National Library of Medicine. Using the “Guided Lessons” paradigm of Anatomic VisualizeR, the student enters a 3D workspace that contains a “Study Guide.” The student uses the study guide to navigate through the 3D workspace, downloading anatomical models of interest, as well as supporting resources like diagrammatic representations, photographic material, and text. Manipulation of the anatomical models is encouraged to provide the student with an intuitive understanding of anatomical relationships. The study guide also incorporates other instructional material necessary for the completion of a given lesson.

Another advanced medical training system based on VR technology is VMET — the virtual medical trainer — jointly developed by the Research Triangle Institute and Advanced Simulation Corp. [Kizakevich et al., 1998]. VMET was developed to provide training in trauma care. The VMET trauma patient simulator (VMET-TPS), which was designed to comply with civilian guidelines for both Basic Trauma Life Support and Advanced Trauma Life Support, incorporates models of (1) physiological systems and functions, (2) dynamic consequences of trauma to these physiological systems, and (3) medical intervention effects on these physiological systems.

VMET provides a multisensory simulation of a trauma patient, including visible, audible, and behavioral aspects of the trauma patient. To maintain cost-effectiveness, VMET is constrained to providing

“virtual spaces” at the site of several injuries, including a penetrating chest wound, a penetrating arm wound, laceration to the arm, and a thigh contusion. Within the virtual spaces, the trainee can experience the physiological effects of the injury and of his intervention in real time, as the physiological engine updates the condition of the wound.

VMET-TPS was designed to train military personnel in trauma care, so it places emphasis on the medical technology currently and foreseeably available to the military. However, VMET-TPS will find applications in civilian teaching hospitals, as well. Partially because of the cost-constraint requirements of the project, the price of VMET should be within reach of many trauma centers.

In another task-specific program at the Fraunhofer Institute, researchers have been developing an ultrasonic probe training system based on VR components called the UltraTrainer [Stallkamp and Walper, 1998]. UltraTrainer uses a Silicon Graphics workstation and monitor to present images drawn from a database of real ultrasonograms, a Polhemus tracker to determine the position of the user's hand, a joystick representation of the ultrasound probe, and an ultrasound phantom to provide probe position/orientation feedback to the trainee. In using the UltraTrainer, the trainee moves the ultrasound probe against the phantom, which is used in this system as a representation of the virtual patient's body. On the monitor, the trainee sees an image of the probe in relation to the phantom, showing the trainee the position and orientation of the probe with respect to the virtual patient.

The Polhemus tracker determines and records the real-space position of the virtual ultrasound probe, and this tracker information is then used to extract stored ultrasonograms from a database of images. An ultrasonic image of the appropriate virtual scanfield is presented on the monitor in accordance with the position of the virtual probe on the phantom. As the probe is moved on the phantom, new virtual scanfields are extracted from the database and presented on the monitor. The UltraTrainer is able to present sequential virtual scanfields rapidly enough for the trainee to perceive the virtual ultrasonography as occurring in real time.

Planned improvements to the UltraTrainer include a larger database of stored sonograms that can be customized for different medical specialties, and a reduction in cost by porting the system to a PC and by using a less expensive tracking system. These improvements should allow the UltraTrainer to be accessed by a broader range of users and to move from the laboratory to the classroom, or even to the home.

Three groups of researchers have taken different approaches to developing VR-based training systems for needle insertion, each based on feedback to a different sensory system. At Georgetown University, Lathan and associates [1998] have produced a spine biopsy simulator based on visual feedback; a team from Ohio State University and the Ohio Supercomputer Center have demonstrated an epidural needle insertion simulator based on force feedback [Heimenz et al., 1998]; and Computer Aided Surgery in New York has developed a blind needle biopsy placement simulator that uses 3D auditory feedback [Wenger and Karron, 1998]. Each of these innovative systems draws on technological advances in VR. In the aggregate, they disclose that, given appropriate cognitive constructs, humans are capable of using diverse sensory input to learn very demanding tasks. Imagine how effective VR could be in training complex tasks if all of the sensory information could be integrated in a single system. That is currently one of the goals of the VR community.

### **18.4.3 Anatomical Imaging and Medical Image Fusion**

An anatomically keyed display with real-time data fusion is currently in use at NYU Medical Center's Department of Neurosurgery. The system allows both preoperative planning and real-time tumor visualization [Kall, 1994; Kelly, 1994]. The technology offers a technique for surgeons to plan and simulate the surgical procedure beforehand in order to reach deep-seated or centrally located brain tumors. The imaging method (volumetric stereotaxis) gathers, stores, and reformats imaging-derived, three-dimensional volumetric information that defines an intracranial lesion (tumor) with respect to the surgical field.

Computer-generated information is displayed intraoperatively on computer monitors in the operating room and on a “heads up” display mounted on the operating microscope. These images provide surgeons with a CT (computed tomography) and MRI defined map of the surgical field area scaled to actual

size and location. This guides the surgeon in finding and defining the boundaries of brain tumors. The computer-generated images are indexed to the surgical field by means of a robotics-controlled stereotactic frame which positions the patient's tumor within a defined targeting area. Simulated systems using VR models are being advocated for high risk techniques, such as the alignment of radiation sources to treat cancerous tumors. Where registration of virtual and real anatomical features is not an issue, other display technologies can be employed. Two recent examples, based on totally different display modalities, are described later.

Parsons and Rolland [1998] developed a nonintrusive display technique that projects images of virtual inclusions such as tumors, cysts, or abscesses, or other medical image data into the surgeon's field of view on demand. The system relies on retroreflective material, perhaps used as a backing for the surgeon's glove or on a surgical instrument, to provide an imaging surface upon which can be presented images extracted from 2D data sources, for example MRI scans. The surgeon can access the data by placing the retroreflective screen, for example, his gloved hand, in the path of an imaging beam. The image of the virtual MRI scan, for example, will appear superimposed along the surgeon's line of sight. Although image registration is not currently possible with this real-time display system, the system does provide a means for the clinician to access critical information without turning to view a monitor or other screen.

For displaying volumetric data, Senger [1998] devised a system based on the FakeSpace Immersive Workbench™ and position-tracked StereoGraphics CrystalEyes™ that presents stereoscopic images derived from CT, MRI, and the Visible Human data sets. The viewer can interact with the immersive data structure through the use of a position/orientation sensed probe. The probe can be used first to identify a region of interest within the anatomical data set and then to segment the data so that particular anatomical features are highlighted. The probe can also be used to "inject" digital stain into the data set and to direct the propagation of the stain into structures that meet predetermined parameters, such as voxel density, opacity, etc. Through the use of the probe, the vasculature, fascia, bone, etc. may be selectively stained. This imaging system takes advantage of the recent advances in VR hardware and software, the advent of programs such as the National Library of Medicine's Visible Human Project, and significant cost reductions in computational power to make it feasible for medical researchers to create accurate, interactive 3D human anatomical atlases.

Suzuki and colleagues [1998] have pushed virtual anatomical imaging a step further by including the temporal domain. In 1987, Suzuki, Itou, and Okamura developed a 3D human atlas based on serial MRI scans. Originally designed to be resident on a PC, the 3D Human Atlas has been upgraded during the last decade to take advantage of major advances in computer graphics. The latest atlas is based on composite super-conducting MRI scans at 4 mm intervals at 4 mm pitch of young male and female humans. In addition to volume and surface rendering, this atlas is also capable of dynamic cardiac imaging.

Rendered on a Silicon Graphics Onyx Reality Engine, this atlas presents volumetric images at approximately 10 frames per second. The user interface allows sectioning of the anatomical data along any plane, as well as extracting organ surface information. Organs can be manipulated individually and rendered transparent to enable the user to view hidden structures. By rendering the surface of the heart transparent, it is possible to view the chambers of the heart in 4D at approximately 8 frames per second. Suzuki and colleagues plan to distribute the atlas over the internet so that users throughout the world will be able to access it.

Distribution of volumetric medical imagery over the Internet through the world wide web (WWW) has already been examined by Hendin and colleagues [1998]. These authors relied on the virtual reality modeling language (VRML) and VRMLscript to display and interact with the medial data sets, and they used a Java graphical user interface (GUI) to preserve platform independence. They conclude that it is currently feasible to share and interact with medical image data over the WWW.

Similarly, Silverstein et al. [1998] have demonstrated a system for interacting with 3D radiologic image data over the Internet. While they conclude that the Web-based system is effective for transmitting useful imagery to remote colleagues for diagnosis and pretreatment planning, it does not supplant the requirement that a knowledgeable radiologist examine the 2D tomographic images. This raises the question of the effectiveness of the display and interaction with virtual medical images. The perceived effectiveness

of VR-based anatomical imaging systems similar to those described earlier, has been assessed by Oyama and colleagues [1998]. They created virtual environments consisting of 3D images of cancerous lesions and surrounding tissue, derived from CT or MRI scans, and presented these environments to clinicians in one of three modes. The cancers were from the brain, breast, lung, stomach, liver, and colon, and the presentation modes were either as surface-rendered images, real-time volume-rendered images, or editable real-time volume-rendered images. Clinicians had to rate the effectiveness of the three modes in providing them with information about (1) the location of the cancer, (2) the shape of the cancer, (3) the shape of fine vessels, (4) the degree of infiltration of surrounding organs, and (5) the relationship between the cancer and normal organs. In each of the five categories, the clinicians rated the editable real-time volume-rendered images as superior to the other modes of presentation. From the study, the authors conclude that real-time surface rendering, while applicable to many areas of medicine, is not suitable for use in cancer diagnosis.

#### 18.4.4 Ergonomics, Rehabilitation, and Disabilities

Virtual reality offers the possibility to better shape a rehabilitative program to an individual patient. Greenleaf [1994] has theorized that the rehabilitation process can be enhanced through the use of VR technology. The group is currently developing a VR-based rehabilitation workstation that will be used to (1) decompose rehabilitation into small, incremental functional steps to facilitate the rehabilitation process; and (2) make the rehabilitation process more realistic and less boring, thus enhancing motivation and recovery of function.

DataGlove and DataSuit technologies were originally developed as control devices for VR, but through improvements they are now being applied to the field of functional evaluation of movement and to rehabilitation in a variety of ways. One system, for example, uses a glove device coupled with a force feedback system — The Rutgers Master (RM-I) — to rehabilitate a damaged hand or to diagnose a range of hand problems [Burdea et al., 1995, 1997]. The rehabilitation system developed by Burdea and colleagues uses programmable force feedback to control the level of effort required to accomplish rehabilitative tasks. This system measures finger-specific forces while the patient performs one of several rehabilitative tasks, including ball squeezing, DigiKey exercises, and peg insertion.

Another system under development — The RM II — incorporates tactile feedback to a glove system to produce feeling in the fingers when virtual objects are “touched” [Burdea, 1994]. In order to facilitate accurate goniometric assessment, improvements to the resolution of the standard DataGlove have been developed [Greenleaf, 1992]. The improved DataGlove allows highly accurate measurement of dynamic range of motion of the fingers and wrist and is in use at research centers such as Johns Hopkins and Loma Linda University to measure and analyze functional movements.

Adjacent to rehabilitation evaluation systems are systems utilizing the same measurement technology to provide ergonomic evaluation and injury prevention. Workplace ergonomics has already received a boost from new VR technologies that enable customized workstations tailored to individual requirements [Greenleaf, 1994]. In another area, surgical room ergonomics for medical personnel and patients is projected to reduce the hostile and complicated interface among patients, health care providers, and surgical spaces [Kaplan, 1994].

Motion analysis software (MAS) can assess and analyze upper extremity function from dynamic measurement data acquired by the improved DataGlove. This technology not only provides highly objective measurement, but also ensures more accurate methods for collecting data and performing quantitative analyses for physicians, therapists, and ergonomics specialists involved in job site evaluation and design. The DataGlove/MAS technology is contributing to a greater understanding of upper extremity biomechanics and kinesiology. Basic DataGlove technology coupled with VR media will offer numerous opportunities for the rehabilitation sector of the medical market, not the least of which is the positive implication for enhancing patient recovery by making the process more realistic and participatory.

One exciting aspect of VR technology is the inherent ability to enable individuals with physical disabilities to accomplish tasks and have experiences otherwise denied to them. The strategies currently employed

for disability-related VR research include head-mounted displays; position/orientation sensing; tactile feedback; eye tracking; 3D sound systems; data input devices; image generation; and optics. For physically disabled persons, VR will provide a new link to capabilities and experiences heretofore unattainable, such as:

- An individual with cerebral palsy who is confined to a wheelchair can operate a telephone switchboard, play hand ball, and dance [Greenleaf, 1994] within a virtual environment.
- Patients with spinal cord injury or CNS dysfunction can relearn limb movements through adaptive visual feedback in virtual environments [Steffin, 1997].
- Disabled individuals can be in one location while their “virtual being” is in a totally different location. This opens all manner of possibilities for participating in work, study, or leisure activities anywhere in the world without leaving home.
- Physically disabled individuals could interact with real world activities through robotic devices they control from within the virtual world.
- Blind persons could practice and plan in advance navigating through or among buildings if the accesses represented in a virtual world were made up of three-dimensional sound images and tactile stimuli [Max and Gonzalez, 1997].

One novel application of VR technology to disabilities has been demonstrated by Inman [1994a,b; 1996] who trained handicapped children to operate wheelchairs without the inherent dangers of such training. Inman trained children with cerebral palsy or orthopedic impairments to navigate virtual worlds that contained simulated physical conditions that they would encounter in the real world. By training in a virtual environment, the children acquired an appreciation of the dynamics of their wheelchairs and of the dangers that they might encounter in the real world, but in a safe setting. The safety aspect of VR training is impossible to achieve with other training technologies.

VR will also enable persons with disabilities to experience situations and sensations not accessible in a physical world. Learning and working environments can be tailored to specific needs with VR. For example, since the virtual world can be superimposed over the real world, a learner could move progressively from a highly supported mode of performing a task in the virtual world, through to performing it unassisted in the real world. One project, “Wheelchair VR” [Trimble, 1992], is a highly specialized architectural software being developed to aid in the design of barrier-free building for persons with disabilities.

VR also presents unique opportunities for retraining persons who have incurred neuropsychological deficits. The cognitive deficits associated with neurophysiological insults are often difficult to assess and for this and other reasons, not readily amenable to treatment. Several groups have begun to investigate the use of VR in the assessment and retraining of persons with neuropsychological cognitive impairments. Pugnetti and colleagues [1995a,b, 1996] have begun to develop VR-based scenarios based on standardized tests of cognitive function, for example, card-sorting tasks. Because the tester has essentially absolute control over the cognitive environment in which the test is administered, the effects of environmental distractors can be both assessed and controlled. Initial tests by the Italian group suggests that VR-based cognitive tests offer great promise for both evaluation and retraining of brain-injury-associated cognitive deficits.

Other groups have been developing cognitive tests based on mental rotation of virtual objects [Buchwalter and Rizzo, 1997; Rizzo and Buchwalter, 1997] or spatial memory of virtual buildings [Attree et al., 1996]. Although VR technology shows promise in both the assessment and treatment of persons with acquired cognitive deficits, Buchwalter and Rizzo find that the technology is currently too cumbersome, too unfamiliar, and has too many side effects to allow many patients to benefit from its use.

Attree and associates, however, have begun to develop a taxonomy of VR applications in cognitive rehabilitation. Their study examined the differences between active and passive navigation of virtual environments. They report that active navigation improves spatial memory of the route through the virtual environment, while passive navigation improves object recognition for landmarks within the virtual environment. This report sends a clear message that VR is capable of improving cognitive function, but that much more work is required to understand how the technology interacts with the human psyche.

One researcher who is actively pursuing this understanding is Dorothy Strickland [1995, 1996], who has developed a virtual environment for working with autistic children. Strickland's premise is that VR technology allows precise control of visual and auditory stimuli within virtual environments. Frequently, autistic children find the magnitude of environmental stimuli overwhelming, so it is difficult for them to focus. Strickland has developed a sparse virtual environment into which stimuli can be introduced as the autistic child becomes capable of handling more environmental stimulation. Essentially, she produces successive approximations to a real environment at a rate that the autistic child can tolerate. Her work has shown that autistic children can benefit greatly by exposure to successively richer environments and that the advances that they make in virtual environments transfer to the real world.

Max and Burke [1997], also using VR with autistic children, report that contrary to expectations, their patients were able to focus on the virtual environment, rather than "fidgeting" as they are prone to do in other environments. These researchers also found that in the absence of competing acoustic stimuli, autistic children were drawn to loud music and shunned soft choral music. These findings may provide important insights into the etiology of autism that could not be observed in the "real world" setting.

### 18.4.5 Telesurgery and Telemedicine

Telepresence is the "sister field" of VR. Classically defined as the ability to act and interact in an off-site environment by making use of VR technology, telepresence is emerging as an area of development in its own right. Telemedicine (the telepresence of medical experts) is being explored as a way to reduce the cost of medical practice and to bring expertise into remote areas [Burrow, 1994; Rosen, 1994; Rovetta et al., 1997; Rissam et al., 1998].

Telesurgery is a fertile area for development. On the verge of realization, telesurgery (remote surgery) will help resolve issues that can complicate or compromise surgery, among them:

- The patient is too ill or injured to be moved for surgery
- A specialist surgeon is located at some distance from the patient requiring specialized attention
- Accident victims may have a better chance of survival if immediate, on-the-scene surgery can be performed remotely by an emergency room surgeon at a local hospital
- Soldiers wounded in battle could undergo surgery on the battlefield by a surgeon located elsewhere

The surgeon really does operate — on flesh, not a computer animation. And while the distance aspect of remote surgery is a provocative one, telepresence is proving an aid in nonremote surgery as well. It can help surgeons gain dexterity over conventional methods of manipulation. This is expected to be particularly important in laparoscopic surgery. For example, suturing and knot-tying will be as easy to see in laparoscopic surgery as it is in open surgery because telepresence enables the surgery to look and feel like open surgery.

As developed at SRI International [Satava 1992; Hill et al., 1995, 1998], telepresence not only offers a compelling sense of reality for the surgeon, but also allows the surgeon to perform the surgery according to the usual methods and procedures. There is nothing new to learn. Hand motions are quick and precise. The visual field, instrument motion, and force feedback can all be scaled to make microsurgery easier than it would be if the surgeon were at the patient's side. While the current technology has been implemented in prototype, SRI and Telesurgical Corporation, based in Redwood City, California, are collaborating to develop a full system based on this novel concept.

The system uses color video cameras to image the surgical field in stereo, which the remote surgeon views with stereo shutter glasses. The remote surgeon grasps a pair of force-reflecting 6-DOF remote manipulators linked to a slaved pair of end effectors in the surgical field. Coordinated visual, auditory, and haptic feedback from the end effectors provides the remote surgeon with a compelling sense of presence at the surgical site.

Because the remote manipulators and end effectors are only linked electronically, the gain between them can be adjusted to provide the remote surgeon with microsurgically precise movement of the slaved instruments with relatively gross movement of the master manipulators. Researchers at SRI

have demonstrated the microsurgery capabilities of this system by performing microvascular surgery on rats.

Again, because only an electronic link exists between manipulator and end effector, separation of the remote surgeon and the surgical field can be on a global scale. To demonstrate this global remote surgery capability, Rovetta and colleagues [1998] established Internet and ISDN networks between Monterey, California, and Milan, Italy, and used these networks to remotely control a surgical robot. By manipulating controls in Monterey, Professor Rovetta was able to perform simulated biopsies on liver, prostate, and breasts in his laboratory in Milan, Italy. Using both an Internet and ISDN network facilitated the transmission of large amounts of image data and robotic control signals in a timely manner.

Prior to the telesurgery demonstration between Monterey and Milan, Rovetta and colleagues [1997] established a link between European hospitals and hospitals in Africa as part of the Telehealth in Africa Program of the European Collaboration Group for Telemedicine. Among the objectives of this program was a demonstration of the feasibility of transmitting large amounts of medical data including x-ray and other diagnostic images, case histories, and diagnostic analyses. Once established, the data link could be used for teleconsulting and teletraining.

Teleconsulting is becoming commonplace. Within the last year, the U.S. Department of Veteran Affairs has established a network to link rural and urban Vet Centers. This network, which will initially link 20 Vet Centers, will provide teleconsultation for chronic disease screening, trauma outreach, and psychosocial care. In Europe, where telemedicine is making great strides, the Telemedical Information Society has been established [see Marsh, 1998, for additional information]. At the International Telemedical Information Society '98 Conference held in Amsterdam in April 1998, a number of important issues pertaining to teleconsultation were addressed. Among these were discussions about the appropriate network for telemedicine, for example, the WWW, ATM, and privacy and liability issues.

Privacy, that is security of transmitted medical information, will be a continuing problem as hackers hone their ability to circumvent Internet security [Radesovich, 1997]. Aslan and colleagues [1998] have examined the practicality of using 128-bit encryption for securing the transmission of medical images. Using software called Photomailer™, Aslan at Duke Medical Center and his colleagues at Boston University Medical Center and Johns Hopkins encrypted 60 medical images and transmitted them over the Internet. They then attempted to access the encrypted images without Photomailer™ installed on the receiving computer. They reported complete success and insignificant increases in processing time with the encrypting software installed.

## 18.4.6 Behavioral Evaluation and Intervention

VR technology has been successfully applied to a number of behavioral conditions over the last few years. Among the greatest breakthroughs attained through the use of this technology is the relief of akinesia, a symptom of Parkinsonism wherein a patient has progressively greater difficulty initiating and sustaining walking. The condition can be mitigated by treatment with drugs such as L-dopa, a precursor of the natural neural transmitters dopamine, but usually not without unwanted side effects. Now, collaborators at the Human Interface Technology Laboratory at the University of Washington, along with the University's Department of Rehabilitation Medicine and the San Francisco Parkinson's Institute, are using virtual imagery to simulate an effect called kinesia paradoxa, or the triggering of normal walking behavior in akinetic Parkinson's patients [Weghorst, 1994].

Using a commercial, field-multiplexed, "heads-up" video display, the research team has developed an approach that elicits near-normal walking by presenting collimated virtual images of objects and abstract visual cues moving through the patient's visual field at speeds that emulate normal walking. The combination of image collimation and animation speed reinforces the illusion of space-stabilized visual cues at the patient's feet. This novel, VR-assisted technology may also prove to be therapeutically useful for other movement disorders.

In the area of phobia intervention, Lamson [1994, 1997] and Lamson and Meisner [1994] has investigated the diagnostic and treatment possibilities of VR immersion on anxiety, panic, and phobia of heights. By immersing both patients and controls in computer-generated situations, the researchers were able to expose the subjects to anxiety provoking situations (such as jumping from a height) in a controlled manner. Experimental results indicated a significant subject habituation and desensitization through this approach, and the approach appears clinically useful.

The effectiveness of VR as a treatment for acrophobia has been critically examined by Rothbaum and associates [1995a,b]. They used a procedure in which phobic patients were immersed in virtual environments that could be altered to present graded fear-inducing situations. Patient responses were monitored and used to modify the virtual threats accordingly. Rothbaum et al. report that the ability to present graded exposure to aversive environments through the use of VR technology provides a very effective means of overcoming acrophobia. Transfer to the real world was quite good.

The use of VR technology in the treatment of phobias has expanded in recent years to include fear of flying [Rothbaum et al., 1996; North et al., 1997], arachnophobia [Carlin et al., 1997], and sexual dysfunction [Optale et al., 1998]. In each of these areas, patients attained a significant reduction in their phobias through graded exposure to fear-provoking virtual environments. In the treatment of arachnophobia, Carlin and associates devised a clever synthesis of real and virtual environments to desensitize patients to spiders. Patients viewed virtual spiders while at the same time touching the simulated fuzziness of a spider. The tactile aspect of the exposure was produced by having the patient touch a toupé.

Before leaving the subject of VR treatment of phobias, a word of caution is necessary. Bloom [1997] has examined the application of VR technology to the treatment of psychiatric disorders and sounds a note of warning. Bloom notes the advances made in the treatment of anxiety disorders, but also points out that there are examples of physiological and psychological side effects from immersion in VR. While the major side effects tend to be physiological, mainly simulator sickness and Sopte Syndrome (malaise, lethargy), psychological maladaptations, such as "... unpredictable modifications in perceptions of social context ..." and "... fragmentation of self" [Bloom, 1997] reportedly occur.

## 18.5 Summary

---

VR tools and techniques are being developed rapidly in the scientific, engineering, and medical areas. This technology will directly affect medical practice. Computer simulation will allow physicians to practice surgical procedures in a virtual environment in which there is no risk to patients, and where mistakes can be recognized and rectified immediately by the computer. Procedures can be reviewed from new, insightful perspectives that are not possible in the real world.

The innovators in medical VR will be called upon to refine technical efficiency and increase physical and psychological comfort and capability, while keeping an eye on reducing costs for health care. The mandate is complex, but like VR technology itself, the possibilities are very exciting. While the possibilities — and the need — for medical VR are immense, approaches and solutions using new VR-based applications require diligent, cooperative efforts among technology developers, medical practitioners, and medical consumers to establish where future requirements and demand will lie.

## Defining Terms

For an excellent treatment of the state-of-the-art of VR and its taxonomy, see the ACM SIGGRAPH publication "Computer Graphics," Vol. 26, #3, August 1992. It covers the U.S. Government's National Science Foundation invitational workshop on Interactive Systems Program, March 23 to 24, 1992, which served to identify and recommend future research directions in the area of virtual environments. A more in-depth exposition of VR taxonomy can be found in the MIT Journal "Presence," Vol. 1 #2.

**T**HE EVOLUTION OF TECHNOLOGICAL ADVANCES in infrared sensor technology, image processing, “smart” algorithms, knowledge-based databases and their overall system integration has resulted in new methods of research and use in medical infrared imaging. The development of infrared cameras with focal plane arrays not requiring cooling added a new dimension to this modality. New detector materials with improved thermal sensitivity are now available and production of high-density focal plane arrays (640 × 480) have been achieved. Advance read-out circuitry using on-chip signal

processing is in common use. These breakthroughs permit low-cost and easy-to-use camera systems with thermal sensitivity less than 50 milli-kelvin degrees, as well as spatial resolution of 25 to 50  $\mu\text{m}$ , given the appropriate optics. Another important factor is the emerging interest in the development of smart image processing algorithms to enhance the interpretation of thermal signatures. In the clinical area, new research addresses the key issues of diagnostic sensitivity and specificity of infrared imaging. Efforts are underway to achieve quantitative clinical data interpretation in standardized diagnostic procedures. For this purpose, clinical protocols are emphasized.

New concepts such as dynamic thermal imaging and thermal texture mapping (thermal tomography) and thermal multi-spectral imaging are being implemented in clinical environments. Other areas like three-dimensional infrared are being investigated.

Some of these new ideas, concepts, and technologies are covered in this section. We have assembled a set of chapters which range in content from historical background, concepts, clinical applications, standards, and infrared technology.

Chapter 19 deals with worldwide advances in and a guide to thermal imaging systems for medical applications. Chapter 20 presents an historical perspective and the evolution of thermal imaging. Chapter 21 deals with the physiological basis of the thermal signature and its interpretation in a medical setting. Chapters 22 and 23 cover innovative concepts such as dynamic thermal imaging and thermal tomography which enhance the clinical utility leading to improved diagnostic capability. Chapter 24 discusses the physics of thermal radiation theory and the pathophysiology as related to infrared imaging. Chapters 25 and 26 expose the fundamentals of infrared breast imaging, equipment considerations, early detection and the use of infrared imaging in a multi-modality setting. Chapters 27 and 28 are on innovative image processing techniques for the early detection of breast cancer. Chapter 29 presents biometrics, a novel method for facial recognition. Today, this technology is of utmost importance in the area of homeland security and other applications. Chapter 30 deals with infrared monitoring of therapies multi-spectral optical imaging in Kaposi's Sarcoma investigations at NIH. Chapters 31 to 34 deal with the use of infrared in various clinical applications: surgery, dental, skeletal and neuromuscular diseases, as well as the quantification of the TAU image technique in the relevance and stage of a disease. Chapter 35 is on infrared imaging in veterinary medicine. Chapter 36 discusses the complexities and importance of standardization, calibration and protocols for effective and reproducible results. Chapters 37 to 39 are comprehensive chapters on technology and hardware including detectors, detector materials, uncooled focal plane arrays, high performance systems, camera characterization, electronics for on-chip image processing, optics and cost reduction designs.

This section will be of interest to both the medical and biomedical engineering communities. It could provide many opportunities for developing and conducting multi-disciplinary research in many areas of medical infrared imaging. These range from clinical quantification, to intelligent image processing for enhancement of the interpretation of images, and for further development of user-friendly high resolution thermal cameras. These would enable the wide use of infrared imaging as a viable, non-invasive, low cost first-line detection modality.

## Acknowledgments

I would like to acknowledge each and every author in this section for their excellent contributions. I am aware of their busy schedules and I appreciate the time they dedicated to the first Infrared Imaging Section to be contained in a *CRC Biomedical Engineering Handbook*.

### 19.1 Introduction

---

Infrared (IR) imaging in medicine has been used in the past but without the advantage of 21st century technology. In 1994, under the Department of Defense (DOD) grants jointly funded by the Office of the Secretary of Defense (OSD-S&T), the Defense Advanced Research Projects Agency (DARPA) and the Army Research Office (ARO), a concerted effort was initiated to re-visit this subject. Specifically, it was to explore the potential of integrating advanced IR technology with “smart” image processing for use in medicine. The major challenges for acceptance of this modality by the medical community were investigated. It was found that the following issues were of prime importance (1) standardization and quantification of clinical data; (2) better understanding of the pathophysiological nature of thermal signatures; (3) wider publication and exposure of medical IR imaging in conferences and leading journals; (4) characterization of thermal signatures through an interactive web-based database; and (5) training in both image acquisition and interpretation.

In the last ten years, significant progress has been made internationally by advancing a thrust for new initiatives worldwide for clinical quantification, international collaboration, and providing a forum

for coordination, discussion, and publication through the following activities (1) medical infrared imaging symposia, workshops, and tracks at IEEE/Engineering in Medicine and Biology Society (EMBS) conferences from 1994 to 2004; (2) three Engineering in Medicine and Biology Magazines (EMBS), Special Issues dedicated to this topic [1–3]; (3) The DOD “From Tanks to Tumors” Workshop [4]. The products of these efforts are documented in final government technical reports [5–8] and IEEE/EMBS Conference Proceedings (1994 to 2004).

Early infrared cameras used a small number of detector elements (1 to 180 individual detectors) which required cryogenic cooling in order to operate effectively without noise. The camera design incorporated a scanning mechanism with mirrors to form the image. Electrical contact was made to each individual detector — a very laborious and time intensive task. The signal leads were brought out of the cryogenic envelope and each individual signal was combined. The processing was performed outside of the focal plane array. This type of camera was heavy in weight, high in power consumption, and very expensive to manufacture. Hence, the technology focused on producing a more efficient, lower-cost system which ultimately led to the un-cooled focal plane array (FPA) type cameras. In the focal plane array camera, the detectors are fabricated in large arrays which eliminates the need for scanning. Electrical contact is made simultaneously to the detector array thus reducing significantly the number of leads through vacuum. Furthermore, the uncooled focal plane array has the potential to accommodate on-chip processing, thus leading to faster operation and fewer leads.

Presently, infrared imaging is used in many different medical applications. The most prominent of these are oncology (breast, skin, etc.), vascular disorders (diabetes DVT, etc.), pain, surgery, tissue viability, monitoring the efficacy of drugs, and therapies; respiratory (recently introduced for testing of SARS).

There are various methods used to acquire infrared images: Static, Dynamic, Passive, and Active — Dynamic Area Telethermometry (DAT), subtraction, etc. [9], Thermal Texture Mapping (TTM),

**TABLE 19.1** Medical applications and methods

Applications	IR Imaging Methods
Oncology (breast, skin, etc)	Static (classical)
Pain (management/control)	Dynamic (DAT, subtraction, etc.)
Vascular Disorders (diabetes, DVT)	Dynamic (Active)
Arthritis / Rheumatism	Thermal Texture Mapping (TTM)
Neurology	Multispectral/Hyperspectral
Surgery (open heart, transplant, etc.)	Multi-modality
Ophthalmic (cataract removal)	Sensor Fusion
Tissue Viability (burns, etc.)	
Dermatological Disorders	
Monitoring Efficacy of drugs and therapies	
Thyroid	
Dentistry	
Respiratory (allergies, SARS)	
Sports and Rehabilitation Medicine

Multispectral/Hyperspectral, Multi-modality, and Sensor Fusion. A list of current applications and infrared imaging methods are listed in Table 19.1. Figure 19.1 and Figure 19.2 illustrate thermal signatures of breast screening and Kaposi Sarcoma.

## 19.2 Worldwide Use of Infrared Imaging in Medicine

### 19.2.1 United States of America and Canada

Infrared imaging is beginning to be reconsidered in the United States, largely due to new infrared technology, advanced image processing, powerful, high speed computers, and exposure of existing research. This is evidenced by the increased number of publications available in open literature and national databases such as “Index Medicus” and “Medline” (National Library of Medicine) on this modality. Currently, there are several academic institutions with research initiatives in infrared imaging. Some of the most prominent are the following: NIH, Johns Hopkins University, University of Houston, University of Texas. NIH has several ongoing programs: vascular disorders (diabetes, Deep Venous Thrombosis), monitoring angiogenesis activity — Kaposi Sarcoma, pain-reflex sympathetic dystrophy, monitoring the efficacy of radiation therapy, organ transplant — perfusion, multi-spectral imaging.

Johns Hopkins University does research in microcirculation, monitoring angiogenic activity in Kaposi Sarcoma and breast screening, laparoscopic IR images — renal disease.

The University of Houston just created an infrared imaging laboratory to investigate with IR the facial thermal characteristics for such applications as lie detection and other behavioral issues (fatigue, anxiety, and fear, etc.).

There are two medical centers specializing in breast cancer research and treatment which use infrared routinely as part of their first line detection system, which also includes mammography and clinical exam. These are: Elliott-Elliott-Head Breast Cancer and Treatment Center, Baton Rouge, LA. And Ville Marie Oncology Research Center, Montreal, Canada. Their centers are fully equipped with all state-of-the-art imaging equipment. These centers are members of the coalition team for the development of a “knowledge-based” database of thermal signatures of the breast with “ground-truth” validation.

### 19.2.2 China

China has a long-standing interest in infrared imaging. More recently, the novel method Thermal Texture Mapping (TTM) has added increased specificity to static imaging. It is known that this method is widely used in this country, but unfortunately there is no formal literature about this important work. This is urgently needed in order for TTM to be exposed and accepted as a viable, effective method by the international community. The clinical results obtained through this method should be published in open literature of medical journals and international conference proceedings. Despite the lack of the availability

of this documentation, introduction of TTM has been made to The National Institutes of Health (NIH). They are now using this method and its camera successfully in detection and treatment in Kaposi Sarcoma (associated with AIDS patients). After further discussions with them, interest has also been shown for its use in the area of breast cancer (detection of angiogenesis). There are further possibilities for high level research for this method in the United States and abroad.

### 19.2.3 Japan

Infrared imaging is widely accepted in Japan by the government and the medical community. More than 1500 hospitals and clinics use IR imaging routinely. The government sets the standards and reimburses clinical tests. Their focus is in the following areas: blood perfusion, breast cancer, dermatology, pain, neurology, surgery (open-heart, orthopedic, dental, cosmetic), sport medicine, and oriental medicine. The main research is performed at the following universities: University of Tokyo — organ transplant; Tokyo Medical and Dental University (skin temperature characterization and thermal properties); Toho University (neurological operation); Cancer Institute hospital (breast cancer). In addition, around forty other medical institutions are using infrared for breast cancer screening.

### 19.2.4 Korea

Began involvement in IR imaging during the early 1990s. More than 450 systems being used in hospitals and medical centers. Primary clinical applications are neurology, back pain/treatment, surgery, and oriental medicine. Yonsei College of Medicine is one of the leading institutions in medical IR imaging research along with three others.

### 19.2.5 United Kingdom

The University of Glamorgan is the center of IR imaging; the School of Computing has a thermal physiology laboratory which focuses in the following areas: medical infrared research, standardization, training (university diploma), “SPORTI” Project funded by the European Union Organization. The objective of this effort is to develop a reference database of normal, thermal signatures from healthy subjects.

The Royal National Hospital of Rheumatic Diseases specializes in rheumatic disorders, occupational health (Raynaud’s Disease, Carpal Tunnel Syndrome, and Sports Medicine).

The Royal Free University College Medical School Hospital specializes in vascular disorders (diabetes, DVT, etc.), optimization of IR imaging techniques, and Raynaud’s Phenomenon).

### 19.2.6 Germany

University of Leipzig uses infrared for open-heart surgery, perfusion and micro-circulation. There are several private clinics and other hospitals that use infrared imaging in various applications.

EvoBus-Daimler Chrysler uses infrared imaging for screening all their employees for wellness/health assessment (occupational health).

InfraMedic, AG, conducts breast cancer screening of women from 20 to 85 years old for the government under a two year grant. Infrared is the sole modality used. Their screening method is called Infrared Regulation Imaging (IRI) (see Figure 19.1).

### 19.2.7 Austria

Ludwig Boltzman Research Institute for Physical Diagnostics has done research in infrared for many years and it publishes the “Thermology International” (a quarterly journal of IR clinical research and instrumentation). This journal contains papers from many Thermology Societies. A recent issue contains the results of a survey of 2003 international papers dedicated to Thermology [10].

The General Hospital, University of Vienna, does research mainly in angiology (study of blood and lymph vessels) diabetic foot (pedobarography).

### 19.2.8 Poland

There has been a more recent rapid increase in the use of infrared imaging for medicine in Poland since the Polish market for IR cameras was opened up. There are more than fifty cameras being used in the following medical centers: Warsaw University, Technical University of Gdansk, Poznan University, Lodz University, Katowice University and the Military Clinical Hospital. The research activities are focused on the following areas.

Active Infrared Imaging, open-heart surgery, quantitative assessment of skin burns, ophthalmology, dentistry, allergic diseases, neurological disorders, plastic surgery, thermal image database for healthy and pathological cases, and multi-spectral imaging (IR, visual, x-ray, ultrasound).

In 1986 the Eurotherm Committee was created by members of the European Community to promote cooperation in the thermal sciences by gathering scientist and engineers working in the area of Thermology. This organization focuses on quantitative infrared thermography and periodically holds conferences and seminars in this field [11].

### 19.2.9 Italy

Much of the clinical use of IR imaging is done under the public health system, besides private clinics. The ongoing clinical work is in the following areas: dermatology (melanoma), neurology, rheumatology, anaesthesiology, reproductive medicine, and sports medicine. The University of G. d'Annunzio, Chieti, has an imaging laboratory purely for research on infrared applications. It collaborates on these projects with other universities throughout Italy.

There are other places, such as Australia, Norway, South America, Russia, etc. that have ongoing research as well.

## 19.3 Infrared Imaging in Breast Cancer

---

In the United States, breast cancer is a national concern. There are 192,000 cases a year; it is estimated that there are 1 million women with undetected breast cancer; presently, the figure of women affected is 1.8 million; 45,000 women die per year. The cost burden of the U.S. healthcare is estimated at \$18 billion per year. The cost for early stage detection is \$12,000 per patient and for late detection it is \$345,000 per patient. Hence, early detection would potentially save \$12B dollars annually — as well as many lives. As a result, the U.S. Congress created “The Congressionally Directed Medical Research Program for Breast Cancer.” Clinical infrared has not as yet been supported through this funding. Effort is being directed toward including infrared. Since 1982, the FDA has approved infrared imaging (Thermography) as an adjunct modality to mammography for breast cancer as shown in Table 19.2.

Ideal characteristics for an early breast cancer detection method as defined by the Congressionally Directed Medical Research Programs on Breast Cancer are listed in Table 19.3. Infrared imaging meets these requirements with the exception of the detection of early lesions at 1,000 to 10,000 cells which has not yet been fully determined.

A program is underway in the United States to develop a prototype web-based database with a collection of approximately 2000 patient thermal signatures to be categorized into three categories: normal, equivocal, and suspicious for developing algorithms for screening and early detection of tumor development.

The origin of this program can be traced back to a 1994 multi-agency DOD grant sponsored by the Director for Research in the Office of the Director, Defense Research and Engineering, the Defense Advanced Research Projects Agency, and the Army Research Office. This grant funded a study to determine the applicability of advanced military technology to the detection of breast cancer — particularly thermal

imaging and automatic target recognition. The study produced two reports, one in 1995 and another in 1998; these studies identified technology, concepts, and ongoing activity that would have direct relevance to a rigorous application of infrared. Rigor was the essential ingredient to further progress. The U.S. effort had been dormant since the 1970s because of the limitations imposed by poor sensors, simplistic imaging processing, lack of automatic target recognition, and inadequate computing power. This was complicated by the fact that the virtues of infrared had been overstated by a few developers.

In 1999, the Director for Research in the Office of the Director, Defense Research and Engineering and the Deputy Assistant Secretary of the Army for Installations and Environment; Environmental Safety and Occupational Health formulated a technology transfer program that would facilitate the use of advanced military technology and processes to breast cancer screening. Funds were provided by the Army and the project was funded through the Office of Naval Research (ONR).

A major milestone in the U.S. program was the Tanks to Tumors workshop held in Arlington, VA, December 4 to 5, 2001. The workshop was co-sponsored by Office of the Director, Defense Research and Engineering, Space and Sensor Technology Directorate; the Deputy Assistant Secretary of the Army for Environment, Safety and Occupational Health; the Defense Advanced Research Projects Agency; and the Army Research Office. The purpose was to explore means for exploiting the technological opportunities in the integration of image processing, web-based database management and development, and infrared sensor technology for the early detection of breast cancer. A second objective was to provide guidance to a program. The government speakers noted that significant military advances in thermal imaging, and automatic target recognition coupled with medical understanding of abnormal vascularity (angiogenesis) offer the prospect of automated detection from one to two years earlier than other, more costly and invasive screening methods.

There were compelling reasons for both military and civilian researchers to attend (1) recognition of breast cancer as a major occupational health issue by key personnel such as Raymond Fatz, Deputy Assistant Secretary of the Army for Installations and Environment; Environmental Safety and Occupational Health; (2) growing use of thermal imaging in military and civilian medicine (especially abroad); (3) maturation of military technology in automatic target recognition (ATR), ATR evaluation, and low cost thermal

imaging; (4) emerging transfer opportunities to and from the military. In particular, ATR assessment technology has developed image data management, dissemination, collaboration, and assessment tools for use by government and industrial developers of ATR software used to find military targets in thermal imagery. Such tools seem naturally suited for adaptation to the creation and use of a national database for infrared breast cancer imagery and the evaluation of screening algorithms that would assist physicians in detecting the disease early. Finally, recent infrared theories developed by civilian physicians indicate that the abnormal vascularity (angiogenesis) associated with the formation of breast tumors may be detected easily by infrared cameras from 1 to 5 years before any other technique. Early detection has been shown to be the key to high survival probability.

The workshop involved specialists and leaders from the military R&D, academic, and medical communities. Together they covered a multidisciplinary range of topics: military infrared sensor technology, automatic target recognition (ATR), smart image processing, database management, interactive web-based data management, infrared imaging for screening of breast cancer, and related medical topics. Three panels of experts considered (1) Image Processing and Medical Applications; (2) Website and Database; (3) Sensor Technology for Medical Applications. A subject area expert led each. The deliberations of each group were presented in a briefing to the plenary session of the final day. Their outputs were quite general; they still apply to the current program and are discussed below for the benefit of all future U.S. efforts.

### **19.3.1 The Image Processing and Medical Applications**

This group focused on the algorithms (ATR approaches) and how to evaluate and use them. It advised that the clinical methods of collection must be able to support the most common ATR approaches, for example, single frame, change detection, multi-look, and anomaly detection. They also provided detailed draft guidelines for controlled problem sets for ATR evaluation. Although they thought a multi-sensor approach would pay dividends, they stressed the need to quantify algorithm performance in a methodical way, starting with approaches that work with single infrared images.

### **19.3.2 Website and Database**

This panel concerned itself with the collection and management of an infrared image database for breast cancer. It looked particularly at issues of data standards and security. It concluded that the OSD supported Virtual Distributed Laboratory (VDL), created within the OSD ATR Evaluation Program, is a very good model for the medical data repository to include collaborative software, image management software, evaluation concepts, data standards, security, bandwidth, and storage capacity. It also advised that camera calibration concepts and phantom targets be provided to help baseline performance and eliminate unknowns. It noted that privacy regulations would have to be dealt with in order to post the human data but suggested that this would complicate but not impede the formation of the database.

### **19.3.3 Sensor Technology for Medical Applications**

The sensor panel started by pointing out that, if angiogenesis is a reliable early indicator of risk, then thermal imaging is ideally suited to detection at that stage. Current sensor performance is fully adequate. The group discussed calibration issues associated with hardware design and concluded that internal reference is desirable to insure that temperature differences are being measured accurately. However, they questioned the need for absolute temperature measurement; the plenary group offered no counter to this. This group also looked at the economics of thermal imaging, and concluded that recent military developments in uncooled thermal imaging systems at DARPA and the Army Night Vision and Electronic Sensing Division would allow the proliferation of infrared cameras costing at most a few thousand dollars each. They cited China's installation of over 60 such cameras. The panel challenged ATR and algorithm developers to look at software methods to help simplify the sensor hardware, for example, frame to frame change detection to replace mechanical stabilization.

Infrared imaging for medical uses is a multidisciplinary technology and must include experts from very different fields if its full potential is to be realized. The Tanks to Tumors workshop is a model for future U.S. efforts. It succeeded in bringing several different communities together — medical, military, academic, industrial, and engineering. These experts worked together to determine how the United States might adopt thermal imaging diagnostic technology in an orderly and demonstrable way for the early detection of breast cancer and other conditions. The panel recommendations will serve to guide the transition of military technology developments in ATR, the VDL, and IR sensors, to the civilian medical community. The result will be a new tool in the war against breast cancer — a major benefit to the military and civilian population. Detailed proceedings of this workshop are available from ACA, Falls Church, VA.

## **19.4 Guide to Thermal Imaging Systems for Medical Applications**

---

### **19.4.1 Introduction**

The purpose of this section is to provide the physician with an overview of the key features of thermal imaging systems and a brief discussion of the marketplace. It assumes that the reader is somewhat familiar with thermal imaging theory and terminology as well as the fundamentals of digital imaging. It contains a brief, modestly technical guide to buying sensor hardware, and a short list of active websites that can introduce the buyer to the current marketplace. It is intended primarily to aid the newcomer, however, advanced workers may also find some of these websites useful in seeking custom or cutting edge capabilities in their quest to better understand the thermal phenomenology of breast cancer.

### **19.4.2 Background**

As discussed elsewhere, the last decade has seen a resurgence of interest in thermal imaging for the early detection of breast cancer and other medical applications, both civilian and military. There was a brief period in the 1970s when thermal imaging became the subject of medical interest. That interest waned due to the combination of high prices and modest to marginal performance. Dramatic progress has been made in the intervening years; prices have dropped thanks to burgeoning military, domestic, and industrial use; performance has improved significantly; and new technology has emerged from Defense investments. Imaging electronics, digitization, image manipulation software, and automatic detection algorithms have emerged. Cameras can be had for prices that range from about \$3,000 on up. Cameras under \$10,000 can provide a significant capability for screening and data collection. The camera field is highly competitive; it is possible to rent, lease, or buy cameras from numerous vendors and manufacturers.

### **19.4.3 Applications and Image Formats**

Currently, thermal imaging is being used for research and development into the phenomenology of breast cancer detection, and for screening and cuing in the multimodal diagnosis and tracking of breast cancer in patients. The least stressful and most affordable is the latter. Here, two types of formats can be of general utility: uncalibrated still pictures and simple uncalibrated video. Such formats can be stored and archived for future viewing. Use of such imagery for rigorous research and development is not recommended. Furthermore, there may be legal issues associated with the recording and collection of such imagery unless it is applied merely as a screening aid to the doctor rather than as a primary diagnostic tool. In other words, such imagery would provide the doctor with anecdotal support in future review of a patient's record. In this mode, the thermal imagery has the same diagnostic relevance as a stethoscope or endoscope, neither of which is routinely recorded in the doctor's office. Imagery so obtained would not carry the same diagnostic weight as a mammogram. Still cameras and video imagers of this kind are quite affordable and compact. They can be kept in a drawer or cabinet and be used for thermal viewing of many types of conditions including tumors, fractures, skin anomalies, circulation, and drug effects, to name a few. The

marketplace is saturated with imagers under \$10,000 that can provide adequate resolution and sensitivity for informal “eyeballing” the thermal features of interest. Virtually any image or video format is adequate for this kind of use.

For medical R&D, in which still imagery is to be archived, shared, and used for the testing of software and medical theories, or to explore phenomenology, it is important to collect calibrated still imagery in lossless archival formats (e.g., the so-called “raw” format that many digital cameras offer). It is thus desirable to purchase or rent a radiometric still camera with uncompressed standard formats or “raw” output that preserves the thermal calibration. This kind of imagery allows the medical center to put its collected thermal imagery into a standard format for distribution to the Virtual Distributed Laboratory and other interested medical centers. There are image manipulation software packages that can transform the imagery if need be. On the other hand, the data can be transmitted in any number of uncompressed formats and transformed by the data collection center. The use of standard formats is critical if medical research centers are to share common databases. There is no obvious need yet for video in R&D for breast cancer, although thermal video is being studied for many medical applications where dynamic phenomena are of interest.

#### 19.4.4 Dynamic Range

The ability of a camera to preserve fine temperature detail in the presence of large scene temperature range is determined by its dynamic range. Dynamic range is determined by the camera’s image digitization and formation electronics. Take care to use a camera that allocates an adequate number of bits to the digitization of the images. Most commercially available cameras use 12 bits or more per pixel. This is quite adequate to preserve fine detail in images of the human body. However, when collecting images, make sure there is nothing in the field of view of the camera that is dramatically cooler or hotter than the subject; that is, avoid scene temperature differences of more than roughly 30°C (e.g., lamps, refrigerators, or radiators in the background could cause trouble). This is analogous to trying to use a visible digital camera to capture a picture of a person standing next to headlights — electronic circuits may bloom or sacrifice detail of the scene near the bright lights. Although 12-bit digitization should preserve fine temperature differences at a 30°C delta, large temperature differences generally stress the image formation circuitry, and undesired artifacts may appear. Nevertheless, it is relatively easy to design a collection environment with a modest temperature range. A simple way to do this is to simply fill the camera field of view with the human subject. Experiment with the imaging arrangement before collecting a large body of imagery for archiving.

#### 19.4.5 Resolution and Sensitivity

The two most important parameters for a thermal sensor are its sensitivity and resolution. The sensitivity is measured in degrees Celsius. Modest sensitivity is on the order of a tenth of a degree Celsius. Good sensitivity sensors can detect temperature differences up to 4 times lower or 0.025°C. This sensitivity is deemed valuable for medical diagnosis, since local temperature variations caused by tumors and angiogenesis are usually higher than this. The temperature resolution is analogous to the number of colors in a computer display or color photograph. The better the resolution, the smoother the temperature transitions will be. If the subject has sudden temperature gradients, those will be attributable to the subject and not to the camera.

The spatial resolution of the sensor is determined primarily by the size of the imaging chip or pixel count. This parameter is exactly analogous to the world of proliferating digital photography. Just as a 4 megapixel digital camera can make sharper photos than a 2 megapixel camera, pixel count is a key element in the design of a medical camera. There are quite economical thermal cameras on the market with 320 × 240 pixels, and the images from such cameras can be quite adequate for informal screening; imagery may appear to be grainy if magnified unless the viewing area or field of view is reduced. By way of example, if the image is of the full chest area, about 18 inches, then a 320 pixel camera will provide the ability to resolve spatial features of about a sixteenth of an inch. If only the left breast is imaged, spatial

features as low as 1/32 inch can be resolved. On the other hand, a  $640 \times 480$  camera can cut these feature sizes in half. Good sensitivity and pixel count ensures that the medical images will contain useful thermal and spatial detail. In summary, although  $320 \times 240$  imagery is quite adequate, larger pixel counts can provide more freedom for casual use, and are essential for R&D in medical centers. Although the military is developing megapixel arrays, they are not commercially available. Larger pixel counts have advantages for consumer digital photography and military applications, but there is no identified, clear need at this time for megapixel arrays in breast cancer detection. Avoid the quest for larger pixel counts unless there is a clear need. Temperature resolution should be a tenth of a degree or better.

### 19.4.6 Calibration

Another key feature is temperature calibration. Many thermal imaging systems are designed to detect temperature differences, not to map calibrated temperature. A camera that maps the actual surface temperature is a radiographic sensor. A reasonably good job of screening for tumors can be accomplished by only mapping local temperature differences. This application would amount to a third eye for the physician, aiding him in finding asymmetries and temperature anomalies — hot or cold spots. For example, checking circulation with thermal imaging amounts to looking for cold spots relative to the normally warm torso. However, if the physician intends to share his imagery with other doctors, or use the imagery for research, it is advisable to use a calibrated camera so that the meaning of the thermal differences can be quantified and separated from display settings and digital compression artifacts. For example, viewing the same image on two different computer displays may result in different assessments. But, if the imagery is calibrated so that each color or brightness is associated with a specific temperature, then doctors can be sure that they viewing relevant imagery and accurate temperatures, not image artifacts.

It is critical that the calibration be stable and accurate enough to match the temperature sensitivity of the camera. Here caution is advised. Many radiometric cameras on the market are designed for industrial applications where large temperature differences are expected and the temperature of the object is well over  $100^\circ\text{C}$ ; for example, the temperature difference may be  $5^\circ\text{C}$  at  $600^\circ\text{C}$ . In breast cancer, the temperature differences of interest are about a tenth of a degree at about  $37^\circ\text{C}$ . Therefore, the calibration method must be relevant for those parameters. Since the dynamic range of the breast cancer application is very small, the calibration method is simplified. More important are the temporal stability, temperature resolution, and accuracy of the calibration. Useful calibration parameters are: of  $0.1^\circ\text{C}$  resolution at  $37^\circ\text{C}$ , stability of  $0.1^\circ\text{C}/\text{h}$  (drift), and accuracy of  $\pm 0.3^\circ\text{C}$ . This means that the camera can measure a temperature difference of  $0.1^\circ\text{C}$  with an accuracy of  $\pm 0.3^\circ\text{C}$  at body temperature. For example, suppose the breast is at  $36.5^\circ\text{C}$ ; the camera might read  $36.7^\circ\text{C}$ .

Two methods of calibration are available — internal and external. External calibration devices are available from numerous sources. They are traceable to NIST and meet the above requirements. Prices are under \$3000 for compact, portable devices. The drawback with external calibration is that it involves a second piece of equipment and more complex procedure for use. The thermal camera must be calibrated just prior to use and calibration imagery recorded, or the calibration source must be placed in the image while data is collected. The latter method is more reliable but it complicates the collection geometry.

Internal calibration is preferable because it simplifies the entire data collection process. However, radiometric still cameras with the above specifications are more expensive than uncalibrated cameras by \$3000 to \$5000.

### 19.4.7 Single Band Imagers

Today there are thermal imaging sensors with suitable performance parameters. There are two distinct spectral bands that provide adequate thermal sensitivity for medical use: the medium wave infrared band (MWIR) covers the electromagnetic spectrum from 3 to  $5 \mu\text{m}$  in wavelength, approximately; the long wave infrared band (LWIR) covers the wavelength spectrum from about 8 to  $12 \mu\text{m}$ . There are advocates for both bands, and neither band offers a clear advantage over the other for medical applications, although

the LWIR is rapidly becoming the most economical sensor technology. Some experimenters believe that there is merit to using both bands.

MWIR cameras are widely available and generally have more pixels, hence higher resolution for the same price. Phenomenology in this band has been quite effective in detecting small tumors and temperature asymmetries. MWIR sensors must be cooled to cryogenic temperatures as low as 77 K. Thermoelectric coolers are used for some MWIR sensors; they operate at 175 to 220 K depending on the design of the imaging chip. MWIR sensors not only respond to emitted radiation from thermal sources but they also sense radiation from broadband visible sources such as the sun. Images in this band can contain structure caused by reflected light rather than emitted radiation. Some care must be taken to minimize reflected light from broadband sources including incandescent light bulbs and sunlight. Unwanted light can cause shadows, reflections, and bright spots in the imagery. Care should be taken to avoid direct illumination of the subject by wideband artificial sources and sunlight. It is advisable to experiment with lighting geometries and sources before collecting data for the record. Moisturizing creams, sweat, and other skin surface coatings should also be avoided.

The cost of LWIR cameras has dropped dramatically since the advent of uncooled thermal imaging arrays. This is a dramatic difference between the current state of the art and what was available in the 1970s. Now, LWIR cameras are being proliferated and can be competitive in price and performance to the thermoelectrically cooled MWIR. Uncooled thermal cameras are compact and have good resolution and sensitivity. Cameras with  $320 \times 240$  pixels can be purchased for well under \$10,000. This year, sensors with  $640 \times 480$  pixels have hit the market. Sensors in this band are far less likely to be affected by shadows, lighting, and reflections. Nevertheless, it is advisable to experiment with viewing geometry, ambient lighting, and skin condition before collecting data for the record and for dissemination.

### 19.4.8 Emerging and Future Camera Technology

There are emerging developments that may soon provide for a richer set of observable phenomena in the thermography for breast cancer. Some researchers are already simultaneously collecting imagery in both the MWIR and LWIR bands. This is normally accomplished using two cameras at the same time. Dual band imagery arguably provides software and physicians with a richer set of observables. Developers of automatic screening algorithms are exploring schemes that compare the images in the two bands and emphasize the common elements of both to get greater confidence in detecting tumors. More sophisticated software (based on neural networks) learns what is important in both bands. New dual band technology has emerged from recent investments by the Defense Advanced Research Projects Agency (DARPA). Uncooled detector arrays have been demonstrated that operate in both bands simultaneously. It is likely that larger or well-endowed medical centers can order custom imagers with this capability this year. Contact the Materials Technology Office at DARPA for further information.

Spectroscopic (hyperspectral) imaging in the thermal bands is also an important research topic. Investigators are looking for phenomenology that manifests itself in fine spectral detail. Since flesh is a thermally absorptive and scattering medium, it may be possible to detect unique signatures that help detect tumors. Interested parties should ask vendors if such cameras are available for lease or purchase.

Some researchers are using multiple views and color to attempt to enhance tomographic imaging processes and to image to greater depths using physical models of the flesh and its thermal profiles at different wavelengths. Contact the principal investigators directly.

### 19.4.9 Summary Specifications

Table 19.4 summarizes the key parameters and their nominal values to use in shopping for a camera.

How to begin. Those who are new to thermal phenomenology should carefully study the material in this handbook. Medical centers, researchers, and physicians seeking to purchase cameras and enter the field may wish to contact the authors or leading investigators mentioned in this handbook for advice before looking for sensor hardware. The participants in the Tanks to Tumors workshop and the MedATR program

may already have the answers. If possible, compare advice from two or more of these experts before moving on; the experts do not agree on everything. They are currently using sensors and software suitable for building the VDL database. They may also be aware of public domain image screening software. Once advice has been collected, the potential buyer should begin shopping at the one or more of the websites listed in this section. Do not rely on the website alone. Most vendors provide contact information so that the purchaser may discuss imaging needs with a consultant. Take advantage of these advisory services to shop around and survey the field. Researchers may also wish to contact government and university experts before deciding on a camera. Finally, many of the vendors below offer custom sensor design services. Some vendors may be willing to lease or loan equipment for evaluation. High-end, leading edge researchers may need to contact component developers at companies such as Raytheon, DRS, BAE, or SOFRADIR to see if the state of the art supports their specific needs.

*Supplier Websites:* The reader is advised that all references to brand names or specific manufacturers do not connote an endorsement of the vendor, producer, or its products. Likewise, the list is not a complete survey; we apologize for any omissions.

## 19.5 Summary, Conclusions, and Recommendations

Today, medical infrared is being backed by more clinical research worldwide where state-of-the-art equipment is being used. Focus must be placed on the quantification of clinical data, standardization, effective

**TABLE 19.4** Summary of Key Camera Parameters

	Application: recording	Application: informal
Format	Digital stills	Video or stills
Compression	None	As provided by mfr
Digitization (dynamic range)	12 bits or more	12 bits nominal
Pixels (array size)	320 × 240 up to 640 × 480	320 × 240
Sensitivity	0.04°C, 0.1°C max.	0.1°C
Calibration accuracy	±0.3°C	Not required
Calibration range	Room and body temperature	Not required
Calibration resolution	0.1°C	Not required
Spectral band	MWIR or LWIR	MWIR or LWIR

training with high quality assurance, collaborations, and more publications in leading peer reviewed medical journals.

For an effective integration of 21st century technologies for IR imaging we need to focus on the following areas:

- IR cameras and systems
- Advanced image processing
- Image analysis techniques
- High speed computers
- Computer-aided detection (CAD)
- Knowledge-based databases
- Telemedicine

Other areas of importance are:

- Effective clinical use
- Protocol-based image acquisition
- Image interpretation
- System operation and calibration
- Training
- Better understanding of the pathophysiological nature of thermal signatures
- Quantification of clinical data

In conclusion, this noninvasive, non-ionizing imaging modality can provide added value to the present multiimaging clinical setting. This functional image measures metabolic activity in the tissue and thus can noninvasively detect abnormalities very early. It is well known that early detection leads to enhanced survivability and great reduction in health care costs. With these becoming exorbitant, this would be of great value. Besides its usefulness at this stage, a second critical benefit is that it has the capability to non-invasively monitor the efficacy of therapies [12].

## The Historical Development of Thermometry and Thermal Imaging in Medicine

---

E. Francis Ring  
Bryan F. Jones  
*University of Glamorgan*

Fever was the most frequently occurring condition in early medical observation. From the early days of Hippocrates, when it is said that wet mud was used on the skin to observe fast drying over a tumorous swelling, physicians have recognised the importance of a raised temperature. For centuries, this remained a subjective skill, and the concept of measuring temperature was not developed until the 16th Century. Galileo made his famous thermoscope from a glass tube, which functioned as an unsealed thermometer. It was affected by atmospheric pressure as a result.

In modern terms we now describe heat transfer by three main modes. The first is conduction, requiring contact between the object and the sensor to enable the flow of thermal energy. The second mode of heat transfer is convection where the flow of a hot mass transfers thermal energy. The third is radiation. The latter two led to remote detection methods.

Thermometry developed slowly from Galileo's experiments. There were Florentine and Venetian glass-blowers in Italy who made sealed glass containers of various shapes, which were tied onto the body surface. The temperature of an object was assessed by the rising or falling of small beads or seeds within the fluid inside the container. Huygens, Roemer, and Fahrenheit all proposed the need for a calibrated scale in the late 17th and early 18th century. Celsius did propose a centigrade scale based on ice and boiling water. He strangely suggested that boiling water should be zero, and melting ice 100 on his scale. It was the Danish biologist Linnaeus in 1750 who proposed the reversal of this scale, as it is known today. Although International Standards have given the term Celsius to the 0 to 100 scale today, strictly speaking it would be historically accurate to refer to degrees Linnaeus or centigrade [1].

The Clinical thermometer, which has been universally used in medicine for over 130 years, was developed by Dr. Carl Wunderlich in 1868. This is essentially a maximum thermometer with a limited scale around the normal internal body temperature of 37°C or 98.4°F. Wunderlich's treatise on body

temperature in health and disease is a masterpiece of painstaking work over many years. He charted the progress of all his patients daily, and sometimes two or three times during the day. His thesis was written in German for Leipzig University and was also translated into English in the late 19th century [2]. The significance of body temperature lies in the fact that humans are homeotherms who are capable of maintaining a constant temperature that is different from that of the surroundings. This is essential to the preservation of a relatively constant environment within the body known as homeostasis. Changes in temperature of more than a few degrees either way is a clear indicator of a bodily dysfunction; temperature variations outside this range may disrupt the essential chemical processes in the body.

Today, there has been a move away from glass thermometers in many countries, giving rise to more disposable thermocouple systems for routine clinical use.

Liquid crystal sensors for temperature became available in usable form in the 1960s. Originally the crystalline substances were painted on the skin that had previously been coated with black paint. Three of four colours became visible if the paint was at the critical temperature range for the subject. Micro-encapsulation of these substances, that are primarily cholesteric esters, resulted in plastic sheet detectors. Later these sheets were mounted on a soft latex base to mould to the skin under air pressure using a cushion with a rigid clear window. Polaroid photography was then used to record the colour pattern while the sensor remained in contact. The system was re-usable and inexpensive. However, sensitivity declined over 1–2 years from the date of manufacture, and many different pictures were required to obtain a subjective pattern of skin temperature [3].

Convection currents of heat emitted by the human body have been imaged by a technique called Schlieren Photography. The change in refractive index with density in the warm air around the body is made visible by special illumination. This method has been used to monitor heat loss in experimental subjects, especially in the design of protective clothing for people working in extreme physical environments.

Heat transfer by radiation is of great value in medicine. The human body surface requires variable degrees of heat exchange with the environment as part of the normal thermo-regulatory process. Most of this heat transfer occurs in the infrared, which can be imaged by electronic thermal imaging [4]. Infrared radiation was discovered in 1800 when Sir William Herschel performed his famous experiment to measure heat beyond the visible spectrum. Nearly 200 years before, Italian observers had noted the presence of reflected heat. John Della Porta in 1698 observed that when a candle was lit and placed before a large silver bowl in church, that he could sense the heat on his face. When he altered the positions of the candle, bowl, and his face, the sensation of heat was lost.

William Herschel, in a series of careful experiments, showed that not only was there a “dark heat” present, but that heat itself behaved like light, it could be reflected and refracted under the right conditions. William’s only son, John Herschel, repeated some experiments after his father’s death, and successfully made an image using solar radiation. This he called a “thermogram,” a term still in use today to describe an image made by thermal radiation. John Herschel’s thermogram was made by focusing solar radiation with a lens onto a suspension of carbon particles in alcohol. This process is known as evaporography [5].

A major development came in the early 1940s with the first electronic sensor for infrared radiation. Rudimentary night vision systems were produced towards the end of the Second World War for use by snipers. The electrons from near-infrared cathodes were directed onto visible phosphors which converted the infrared radiation to visible light. Sniperscope devices, based on this principle, were provided for soldiers in the Pacific in 1945, but found little use.

At about the same time, another device was made from indium antimonide; this was mounted at the base of a small Dewar vessel to allow cooling with liquid nitrogen. A cumbersome device such as this, which required a constant supply of liquid nitrogen, was clearly impractical for battlefield use but could be used with only minor inconvenience in a hospital. The first medical images taken with a British prototype system, the “Pyroscan,” were made at The Middlesex Hospital in London and The Royal National Hospital for Rheumatic Diseases in Bath between 1959 and 1961. By modern standards, these thermograms were very crude.

In the meantime, the cascade image tube, that had been pioneered during World War II in Germany, had been developed by RCA into a multi-alkali photocathode tube whose performance exceeded expectations. These strides in technology were motivated by military needs in Vietnam; they were classified and, therefore, unavailable to clinicians. However, a mark 2 Pyroscan was made for medical use in 1962, with improved images. The mechanical scanning was slow and each image needed from 2 to 5 min to record. The final picture was written line by line on electro-sensitive paper. In the seventies, the U.S. Military sponsored the development of a multi-element detector array that was to form the basis of a real-time framing imager. This led to the targeting and navigation system known as Forward Looking InfraRed (FLIR) systems which had the added advantage of being able to detect warm objects through smoke and fog.

During this time the potential for thermal imaging in medicine was being explored in an increasing number of centres. Earlier work by the American physiologist J. Hardy had shown that the human skin, regardless of colour, is a highly efficient radiator with an emissivity of 0.98 which is close to that of a perfect black body. Even so, the normal temperature of skin in the region of 20 to 30°C generated low intensities of infrared radiation at about 10  $\mu\text{m}$  wavelength [6]. The detection of such low intensities at these wavelengths presented a considerable challenge to the technology of the day. Cancer detection was a high priority subject and hopes that this new technique would be a tool for screening breast cancer provided the motivation to develop detectors. Many centres across Europe, the United States, and Japan became involved. In the United Kingdom, a British surgeon, K. Lloyd Williams showed that many tumours are hot and the hotter the tumour, the worse the prognosis. By this time, the images were displayed on a cathode ray screen in black and white. Image processing by computer had not arrived, so much discussion was given to schemes to score the images subjectively, and to look for hot spots and asymmetry of temperature in the breast. This was confounded by changes in the breast through the menstrual cycle in younger women. The use of false colour thermograms was only possible by photography at this time. A series of bright isotherms were manually ranged across the temperature span of the image, each being exposed through a different colour filter, and superimposed on a single frame of film.

Improvements in infrared technology were forging ahead at the behest of the U.S. Military during the seventies. At Fort Belvoir, some of the first monolithic laser diode arrays were designed and produced with a capability of generating 500 W pulses at 15 kHz at room temperature. These lasers were able to image objects at distances of 3 km. Attention then turned to solid state, gas, and tunable lasers which were used in a wide range of applications.

By the mid-seventies, computer technology made a widespread impact with the introduction of smaller mini and microcomputers at affordable prices. The first "personal" computer systems had arrived. In Bath, a special system for nuclear medicine made in Sweden was adapted for thermal imaging. A colour screen was provided to display the digitised image. The processor was a PDP8, and the program was loaded every day from paper-tape. With computerisation many problems began to be resolved. The images were archived in digital form, standard regions of interest could be selected, and temperature measurements obtained from the images. Manufacturers of thermal imaging equipment slowly adapted to the call for quantification and some sold thermal radiation calibration sources to their customers to aid the standardisation of technique. Workshops that had started in the late 1960s became a regular feature, and the European Thermographic Association was formed with a major conference in Amsterdam in 1974. Apart from a range of physiological and medical applications groups were formed to formulate guidelines for good practice. This included the requirements for patient preparation, conditions for thermal imaging and criteria for the use of thermal imaging in medicine and pharmacology [7,8]. At the IEEE EMBS conference in Amsterdam some twenty years later in 1996, Dr. N. Diakides facilitated the production of a CD ROM of the early, seminal papers on infrared imaging in medicine that had been published in *ACTA Thermographica* and the *Journal of Thermology*. This CD was sponsored by the U.S. Office of Technology Applications, Ballistic Missile Defence Organisation and the U.S. National Technology Transfer Center Washington Operations and is available from the authors at the Medical Imaging Research Group at the University of Glamorgan, U.K. [9]. The archive of papers may also be search online at the Medical Imaging Group's web site [9].

A thermal index was devised in Bath to provide clinicians with a simplified measure of inflammation [10]. A normal range of values was established for ankles, elbows, hands, and knees, with raised values obtained in osteoarthritic joints and higher values still in Rheumatoid Arthritis. A series of clinical trials with non-steroid, anti-inflammatory, oral drugs, and steroid analogues for joint injection was published using the index to document the course of treatment [11].

Improvements in thermal imaging cameras have had a major impact, both on image quality and speed of image capture. Early single element detectors were dependent on optical mechanical scanning. Both spatial and thermal image resolutions were inversely dependent on scanning speed. The Bofors and some American imagers scanned at 1 to 4 frames per sec. AGA cameras were faster at 16 frames per sec, and used interlacing to smooth the image. Multi-element arrays were developed in the United Kingdom and were employed in cameras made by EMI and Rank. Alignment of the elements was critical, and a poorly aligned array produced characteristic banding in the image. Prof. Tom Elliott F.R.S. solved this problem when he designed and produced the first significant detector for faster high-resolution images that subsequently became known as the Signal PROcessing In The Element (Sprite) detector. Rank Taylor Hobson used the Sprite in the high-resolution system called Talytherm. This camera also had a high specification Infrared zoom lens, with a macro attachment. Superb images of sweat pore function, eyes with contact lenses, and skin pathology were recorded with this system.

With the end of the cold war, the greatly improved military technology was declassified and its use for medical applications was encouraged. As a result, the first focal plane array detectors came from the multi-element arrays, with increasing numbers of pixel/elements, yielding high resolution at video frame rates. Uncooled bolometer arrays have also been shown to be adequate for many medical applications. Without the need for electronic cooling systems these cameras are almost maintenance free. Good software with enhancement and analysis is now expected in thermal imaging. Many commercial systems use general imaging software, which is primarily designed for industrial users of the technique. A few dedicated medical software packages have been produced, which can even enhance the images from the older cameras. CTHERM is one such package that is a robust and almost universally usable programme for medical thermography [9]. As standardisation of image capture and analysis becomes more widely accepted, the ability to manage the images and, if necessary, to transmit them over an intranet or internet for communication becomes paramount. Future developments will enable the operator of thermal imaging to use reference images and reference data as a diagnostic aid. This, however, depends on the level of standardisation that can be provided by the manufacturers, and by the operators themselves in the performance of their technique [12].

Modern thermal imaging is already digital and quantifiable, and ready for the integration into anticipated hospital and clinical computer networks.

### 21.1 Overview

---

William Herschel first recognized heat emitted in the infrared (IR) wave spectrum in the 1800s. Medical infrared, popularly known as IR-thermography has utilized this heat signature since the 1960s to measure and map skin temperatures. Our understanding of the regulation of skin blood flow, heat transfers through the tissue layers, and skin temperatures has radically changed during these past 40 years, allowing us to better interpret and evaluate these thermographic measurements. During this same period of time, improved camera sensitivity coupled with advances in focal plan array technology and new developments in computerized systems with assisted image analysis have improved the quality of the noncontact, non-invasive thermal map or thermogram [1–3]. In a recent electronic literature search in Medline using the keywords “thermography” and “thermogram” more than 5000 hits were found [4]. In 2003 alone, there were 494 medical references, 188 basic science, 148 applied science (14 combined with Laser Doppler and

28 combined with ultrasound research), and 47 in biology including veterinary medicine [5]. Further databases and references for medical thermography since 1987 are available [6].

This review will highlight some of the literature and applications of thermography in medical and physiological settings. More specifically, infrared thermography and the structure and functions of skin thermal microcirculation can provide a better understanding of (1) thermoregulation and skin thermal patterns (e.g., comfort zone, influences of heat, cold, and exercise stressors, etc.), (2) assess skin blood perfusion (e.g., skin grafts), (3) observe and diagnose vascular pathologies that manifest thermal disturbances in the cutaneous circulation, (4) evaluate thermal therapies, and (5) monitor patient/subject/athlete's recovery as evidenced by the resumption of normal thermal patterns during the rehabilitation process for some musculoskeletal injuries.

At the outset, it needs to be stressed that an IR image is a visual map of the skin surface temperature that can provide accurate thermal measurement but cannot quantify measurements of blood flow to the skin tissue. It is also important to stress that recorded skin temperatures may represent heat transferred from within the core through various tissue layers to the skin that may be the result of conductive or radiant heat provided from an external thermal stressor. In order to interpret thermographic images and thermal measurement, a basic understanding of physiological mechanisms of skin blood flow and factors that influence heat transfers to the skin must be considered to evaluate this dynamic process. With this understanding, objective data from IR thermography can add valuable information and complement other methodologies in the scientific inquiry and medical practices.

## 21.2 Skin Thermal Properties in Response to Stress

---

The thermal properties of the skin surface can change dramatically to maintain our core temperature within a narrowly defined survival range (cardiac arrest at 25°C to cell denaturation at 45°C) [7]. This remarkable task is accomplished despite a large variability in temperatures both from the hostile environment and internal production of heat from metabolism. Further perturbations to core and skin temperature may result from thermal stressors associated with injury, fever, hormonal milieu, and disease. The skin responds to these thermal challenges by regulating skin perfusion.

During heat exposure or intense exercise, skin blood flow can be increased to provide greater heat dissipating capacity. The thermal properties of the skin combined with increased cutaneous circulation operate as a very efficient radiator of heat (emitted radiant heat of 0.98 compared to a blackbody source of 1.0) [8]. Evaporative cooling of sweat on the skin surface further enhances this heat dissipating process. Under hyperthermic conditions, the skin masterfully combines anatomical structure and physiological function to protect and defend the organism from potentially lethal thermal stressors by regulating heat transfers between core, skin, and environment. When exposed to a cold environment, the skin surface nearly eliminates blood flow and becomes an excellent insulator. Under these hypothermic conditions, our skin functions to conserve our body's core temperature. It accomplishes this by reducing convective heat transfers, minimizing heat losses from the core and lessening the possibility of excessive cooling from the environment.

The ability of the skin to substantially increase blood flow, far in excess of the tissue's metabolic needs, alludes to the tissue's role and potential in heat transfer mechanisms. The nutritive needs of skin tissue has been estimated at 0.2 ml/min per cubic centimeter of skin [9], which is considerably lower than the maximal rate of 24 ml/min per cubic centimeter of skin (estimated from total forearm circulatory measurement during heat stress) [10]. If one were to approximate skin tissue as 8% of the forearm, then skin blood would equate to 250 to 300 ml/100 ml of skin per minute [11]. Applying this flow rate to an estimated skin surface of 1.8 m<sup>2</sup> (average individual), suggests that approximately 8 liters of blood flow could be diverted to the skin to dissipate heat at rate of 1750 W to the environment [12,13]. This increased blood flow required for heat transfers from active muscle tissue and skin blood flow for thermoregulation is made available through the redistribution of blood flow (splanchnic circulatory beds, renal tissues) and increases in cardiac output [14]. The increased cardiac output has been suggested to account for

two-thirds of the increased blood flow needs, while redistribution provides the remaining one-third [15]. Several good reviews are available regarding cutaneous blood flow, cardiovascular function, and thermal stress [14–19].

## 21.3 Regulation of Skin Blood Flow for Heat Transfers

---

In the 1870s, Goltz, Ostromov, and others injected atropine and pilocarpine into the skin to help elucidate the sympathetic neural innervation of the skin tissue for temperature, pressure, pain, and the activation of the sweat glands [20]. The reflex neural regulation of skin blood flow relies on both sympathetic vasoconstrictor and vasodilator controls to modulate internal heat temperature transfers to the skin. The vasoconstrictor system is responsible for eliminating nearly all of the blood flow to the skin during exposure to cold. When exposed to thermal neutral conditions, the vasoconstrictor system maintains the vasomotor tone of the skin vasculature from which small changes in skin blood flow can elicit large changes in heat dissipation. Under these conditions, the core temperature is maintained; mean skin temperature is stable, but dependent upon the extraneous influences of radiant heat, humidity, forced convective airflow, and clothing. A naked individual in a closed room with ambient air temperature between 27 and 28°C can retain thermal equilibrium without shivering or sweating [21]. Slightly dressed individuals are comfortable in a neutral environment with temperatures between 20 and 25°C. This thermoneutral zone provides the basis for the clinical testing standards for room temperatures being set at 18–25°C during infrared thermographic studies. Controlling room test conditions is important when measuring skin temperature responses as changes in ambient temperatures can alter the fraction of flow shared between the musculature and skin [19]. Under the influence of whole body hyperthermic conditions, removal of the vasomotor vasoconstrictor tone can account for 10–20% of cutaneous vasodilation, while the vasodilator system provides the remaining skin blood flow regulation [10]. Alterations in the threshold (onset of vascular response and sweating) and sensitivity (level of response) in vasodilation blood flow control can be related to an individual's level of heat acclimation [22], exercise training [22], circadian rhythm [23,24], and women's reproductive hormonal status [10]. Recent literature suggests that some observed shifts in the reflex control are the result of female reproductive hormones. Both estrogen and progesterone have been linked to menopausal hot flashes [10].

Skin blood flow research has identified differences in reflex sympathetic nerve activation for various skin surface regions. In 1956, Gaskell demonstrated that sympathetic neural activation in the acral regions (digits, lips, ears, cheeks, and palmer surfaces of hands and feet) is controlled by adrenergic vasoconstrictor nerve activity [20]. In contrast, I.C. Roddie in 1957 demonstrated that in nonacral regions, the adrenergic vasoconstrictor activity accounts for less than 25% of the control mechanism [25]. In the nonacral region, the sympathetic nervous system has both adrenergic (vasoconstriction) and nonadrenergic (vasodilator) components. While the vasodilator activity in the nonacral region is well accepted, the vasoconstrictor regulation is not fully understood and awaits the identification of neural cotransmitters that mediate the reductions in blood flow. For a more in-depth discussion of regional sympathetic reflex regulation, see Charkoudian [10] and Johnson and Proppe [13].

A further distinction in blood flow regulation can be found in the existence of arteriovenous anastomoses (AVA) that are principally found in acral tissues but not commonly found in nonacral tissues of the legs, arms, and chest regions [10,26,27]. The AVAs are thick walled, low resistance vessels that provide a direct blood flow route from arterioles to the venules. The arterioles and AVA, under sympathetic adrenergic vasoconstrictor control, modulate and substantially control flow rates to the skin vascular plexuses in these areas. When constricted, blood flow into subcutaneous venous plexus is reduced to a very low level (minimal heat loss); while, when dilated, extremely rapid flow of warm blood into the venous plexus is allowed (maximal heat loss). The skin sites where these vessels are found are among those where skin blood flow changes are discernible to the IR-thermographer. While the AVA are most active during heat stress, their thick walls and high velocity flow rates do not support their significant role in heat transfers to adjoining skin tissue [12].

Localized cooling of the skin surface can cause skin blood flow vasoconstriction induced by the stimulation of the nonadrenergic sympathetic nerves. This localized cooling or challenge can be used as a diagnostic tool by infrared thermographers to identify clinically significant alterations in skin blood flow response. Using a cold challenge test, Francis Ring developed a vasopasticity test for Raynaud's syndrome based on the temperature gradient in the hand following a cold water immersion (20°C for 60 sec) [28]. Challenge testing and IR imaging has also been used to evaluate blood flow thermal patterns in patients with carpal tunnel syndrome pre- and post-surgery [29]. Skin blood flow vasodilation in response to local heating is stimulated by the release of sensory nerve neuropeptides or the nonneural stimulation of the cutaneous arteriole by nitric oxide. Thermographic imagers have exploited this localized warming response to provide a skin blood flow challenge [10].

As stated earlier, conditions of thermal stress from heat exposure and increased metabolic heat from exercise necessitate increases in skin blood flow to transfer the heat to the environment. This could have serious blood pressure consequences if it were not for baroreflex modulation of skin blood flow in regulating both sympathetic vasoconstriction and vasodilation [30,31]. With mild heat stress for 1 h (38 and 46°C, 42% relative humidity), cardiac output was not significantly impacted [32–34]. When exposing the individual to longer duration bouts and higher temperatures, significant changes in cardiac output have been observed. During these hyperthermic bouts, skin blood flow will withdraw vasodilation in nonacral regions in response to situations that displace blood volumes to the legs (lower body negative pressure or upright tilting) [35]. In contrast, under normothermic conditions, skin blood flow will demonstrate a sympathetic vasoconstriction to these same blood volume situations. Thus, it appears that the baroreceptor response can activate either sympathetic pathway. Withdrawing vasodilation under normothermic conditions was not an option in this inactive system [36].

In summary, skin blood flow during whole body thermal stress is regulated by neural reflex control via sympathetic vasoconstriction and vasodilation. There are structural (AVA) and neural mechanisms (vasoconstriction vs. vasodilation) differences between the acral and nonacral regions. During local thermal stress, stimulation of the sensory afferent nerve, nitric oxide stimulation of cutaneous arteriole, and inhibition of sympathetic vasoconstrictor system regulate changes in local blood flow. During thermal stress and increased heat from exercise metabolism, the skin blood flow can be dramatically increased. This increase in skin blood flow is matched to increased cardiac output and peripheral resistance to maintain blood pressure.

## 21.4 Heat Transfer Modeling Equations for Microcirculation

---

The capacity and ability of blood to transfer heat through various tissue layers to the skin can be predicted from models. These models are based on calculations from tissue conductivity, tissue density, tissue specific heat, local tissue temperature, metabolic or externally derived heat sources, and blood velocity. Many current models were derived from the 1948 Pennes model of blood perfusion, often referred to as the “bioheat equation” [9]. The bioheat equation calculates volumetric heat that is equated to the proportional volumetric rate of blood perfusion. The Pennes model assumed that thermal equilibrium occurs in the capillaries and venous temperatures were equal to local tissue temperatures. Both of these assumptions have been challenged in more recent modeling research. The assumption of thermal equilibrium within capillaries was challenged by the work of Chato [37] and Chen and Holmes in 1980 [38]. Based on this vascular modeling for heat transfer, thermal equilibrium occurred in “thermally significant blood vessels” that are approximately 50 to 75  $\mu\text{m}$  in diameter and located prior to the capillary plexus. These thermally significant blood vessels derive from a tree-like structure of branching vessels that are closely spaced in countercurrent pairs. For a historical perspective of heat transfer bioengineering, see Chato in Reference 37 and for a review of heat transfers and microvascular modeling, see Baish in Reference 39.

This modeling literature provides a conceptual understanding of the thermal response of skin when altered by disease, injury, or external thermal stressors to skin temperatures (environment or application of cold or hot thermal sources, convective airflow, or exercise). From tissue modeling, we know that tissue

is only slightly influenced by the deep tissue blood supply but is strongly influenced by the cutaneous circulation. With the use of infrared thermography, the skin temperatures can be accurately quantified and the thermal pattern mapped. However, these temperatures cannot be assumed to represent thermal conditions at the source of the thermal stress. Furthermore, the thermal pattern only provides a visual map of the skin surface in which heat is dissipated throughout the skin's multiple microvascular plexuses.

## 21.5 Cutaneous Circulation Measurement Techniques

---

A brief review of some of the techniques and procedures that have been employed to reveal skin tissue structure, rates and variability of perfusion, and factors that provide regulatory control of blood flow are provided. This serves to inform the reader as to how these measurement techniques have molded our understanding of skin structure and function. It is also important to recognize the advantages and disadvantages each technique brings to our experimental investigations. It is the opinion of the authors that IR thermography can provide complimentary data to information obtained from these other methodologies.

### 21.5.1 Procedures and Techniques

Visual and microscopic views of skin have provided scientists with a structural layout of skin layers and blood flow. Despite our understanding of the structural organization, we still struggle to understand the regulation and functioning of the skin as influenced by the multitude of external and internal stressors. Since ancient times, documents have recorded visible observations made regarding changes to skin color and temperature that underscore some of the skin's functions. These observations include increased skin color and temperature when someone is hyperthermic, skin flushing when embarrassed, and the appearance of skin reddening when the skin is scratched. In contrast, decreases of skin color and temperature are observed during hypothermia, when blood flow is occluded, or during times of circulatory shock. In addition to observations, testing procedures and techniques have been employed in search of an understanding of skin function. Skin blood flow has provided one of the greatest challenges and has been notoriously difficult to record quantitatively in terms of ml/min per gram of skin tissue.

### 21.5.2 Dyes and Stains

Stains and dyes have been a useful tool to investigate the structure of various histological tissue preparations. In 1889 Overton used Florescin, a yellow dye that glows in visible light, to visualize the lipid bilayer membrane structure [40]. Florescin is still used today to illuminate the blood vessel in various tissues. In the early 1900s, August Krogh was able to identify perfused capillaries by staining them with writer's ink before the tissue was excised and observed under the microscope. Using a different approach to observe the structure of skin blood flow, Michael Salmon in the 1930s developed a radio-opaque preservative mixture that was injected into fresh cadavers and produced detailed pictures of the arterial blood flow to skin tissue regions which were mapped for the entire skin surface [41]. Scientists have also used Evans Blue Dye to investigate changes in blood volume by calculating the dilution factor of pre- and post-samples. Evans Blue and Pontamine Sky Blue dyes have also been used to investigate skin microvascular permeability and leakage as induced by various stimuli [42]. A more recent staining technique involves the use of an IR absorbing dye, indocyanine green (ICG). The dye ICG fluoresces with invisible IR light when captured by special cameras sensitive to these light wavelengths. Recent publications have suggested that ICG video angiographies provide qualitative and quantitative data from which clinicians may assess tissue blood flow in burn wounds [43,44].

### 21.5.3 Plethysmography

The rationale for venous occlusion plethysmography (VOP) is that a partially inflated cuff around a limb exceeds the pressure of venous blood flow but does not interfere with arterial blood flow to the limb.

This can be effectively accomplished when the cuff is inflated to a pressure just below diastolic arterial pressure. Consequently, portions of the limb distal to the cuff will swell as blood accumulates. The original VOP technology relied on measuring the rate of swelling as indicated by the displacement volume of the water-filled chamber around the limb. Later, gauges were used to record changes in limb circumference as the limb expanded. Either way, the geometric forces allows one to express the changes in terms of a starting volume, thus scales are labeled as ml/min per 100 ml in the illustrations of VOP data. Unfortunately, the 100 ml reference quantity refers to the whole limb (not the quantity of the skin) and the VOP technique provides discontinuous measurement, usually four measurements per minute. Currently, VOP represents the most reliable quantitative measure of skin blood flow. More recently, a modified plethysmography technique has been developed that equates changes in blood flow to the changes in electrical impedance, when a mild current is introduced into the blood flow and recorded by serially placed electrodes along the limb.

### **21.5.4 Doppler Measurement**

The Doppler Effect describes the shift in wave length frequency or pitch that result when sound or light from any portion of the electromagnetic spectrum are influenced by the distance and directional movement of the object. Both ultrasound and laser Doppler techniques rely on this physical principle to make the skin blood flow measurement. A continuous wave Doppler ultrasound emits a high frequency sound wave from which reflected or echo sounds can be used to calculate the direction of flow and velocity of moving objects (circulating blood cells). When ultrasound equipment is pulsed, the depth of the circulatory flow vessel can be identified. The blood flow is assessed in Doppler units or volts and can be continuously monitored over a small surface area. Similar measurements can be made with the laser Doppler technique, but neither technique is able to yield quantitative blood flow values except through reference data obtained by VOP.

### **21.5.5 Clearance Measurement**

In the 1930s, scientists relied on the thermal conductance method for determining blood flow in tissues. This methodology was based on measurement of heat dissipation in blood flow downstream from a known heat source (thermocouple). The accuracy of the methodology was assumed through strong correlations made with direct drop counting from isolated sheep spleens. However, these blood flow measurements had problems related to trauma associated with the obstruction and insertion of the thermocouple. During the 1950s and 1960s, injection of small amounts of radioactive isotopes was used in an attempt to better quantify skin blood flow [45]. In order to accurately measure skin blood flow, the isotopes had to be freely diffusible and able to cross the capillary endothelium to enter the blood stream. The blood flow measurement (ml blood flow per 100 g of tissue) obtained through this methodology was not reproducible and subjects were exposed to injected radioactive isotope substances.

### **21.5.6 Thermal Skin Measurement**

Physicians and parents have often relied upon touching a child's forehead to identify a fever or elevated temperature. While this is a crude measure of skin temperature, it has demonstrated practical importance. The development of the thermistor has provided quantifiable measurements of the skin surface. This has been extensively used in research related to thermoregulation and in research in which the skin temperature for a particular physiological perturbation must be quantified. Mean skin temperature formulas have been developed in which various regional temperatures (3 to 15 sites) are combined or a weighted mean based on the DuBois formula for surface area is calculated from the regions measured. When measuring skin temperatures under the influence of colder environments, skin temperature distribution is heterogeneous, especially in the acral regions [46]. Under these conditions, the various placements of the thermistor will provide different temperature measurement that may not be indicative of the mean skin temperature for that region. In contrast, the skin surface temperature is more homogeneous under warm environmental

conditions. To provide an accurate measurement, physiologists investigating mean skin temperatures have modified the number of thermistors required during testing as dictated by environmental temperatures [46]. Thermistor attachment to the skin surface is problematic as it creates a microenvironment between the probe, skin, and adhering tape and exerts a pressure on the site. Furthermore, one site placement of the thermistor cannot represent variable responses under conditions and within regions that demonstrate heterogeneous temperature distributions.

Infrared thermography provides a thermal map of the skin surface area by measuring the radiant heat that is emitted. Current IR thermography machines provide accurate skin surface temperatures ( $<0.05^{\circ}\text{C}$ ) that are noninvasive, noncontact measurements through the use of stable detectors. These systems produce high speed–high resolution images from which thermal data can be pictorially and quantitatively stored and analyzed. While IR radiation begins at wavelengths of  $0.7\ \mu\text{m}$ , current IR thermographic imagers are operating at either the mid-range ( $3\text{--}5\ \mu\text{m}$ ) or long range ( $8\text{--}14\ \mu\text{m}$ ) wavelengths [1–3]. At these wavelengths the skin's ability to emit the radiant heat is 0.98 on a scale of 1.0 for a perfect radiator, blackbody surface [8]. IR-thermographers sometimes rely on “challenge tests” in which the skin thermal response is evaluated after cold or hot water immersion, convective airflow, or an exercise bout that alters skin blood flow. Under these thermally challenging conditions, the clinical importance of abnormalities of skin blood flow may be more apparent. However, one must also recognize that as the heat is being transferred through the various layers of skin, some of the heat is dissipated into the adjoining tissues. The heat decay as the blood traverses the layers of tissue and its dispersion pattern within the circulatory plexus of the skin may disguise the origin of the tissue producing the abnormal thermal response.

### 21.5.7 Measurement Techniques and Procedures Summary

Since ancient times, significant progress has been made in the quest to understand the anatomy and physiology of skin blood flow and the thermal heat transfers that are dissipated to the skin surface. Current measurement technologies are unable to quantify skin blood flow per skin tissue area (ml/min per 100 ml skin). At this time, our best estimations of skin blood flow come from venous occlusion plethysmography. VOP provides discontinuous blood flow measurements based on tissue perfusion of a whole limb extremity. In recent years, laser Doppler blood flow measures have been popular when investigating more localized tissue areas, but this technique must be calibrated through the data obtained by plethysmography. In the quest to understand skin surface heat transfers, noncontact IR thermography provides researchers with accurate measures of skin temperature for specific locations and thermal maps of regions of interest. Thermographic images provide spatial and temporal changes in skin temperature that are representative of spatial and temporal changes in perfusion. However, the scientist and clinician should be aware of blood–skin heat transfer properties prior to interpreting and evaluating the thermal responses of skin perfusion or investigating pathologies that are thermally transferred to the skin.

## 21.6 Objective Thermography

---

The main focus of this section is to present some specific examples to show that IR thermal imaging is a useful, objective tool for medical and physiological-based investigations. Although IR thermal imaging cannot determine quantitative measurements of blood flow, this imaging can quantify skin thermal measurement that can be correlated to qualitative evaluations of skin blood flow. As with any technique, it is imperative for the IR thermographer to understand the anatomical and dynamic physiological features (e.g., vasomotor activity) of the blood vessels involved in skin circulation in order to interpret skin temperature responses. This is particularly important in situations where skin blood flow and temperature are responding to some external or internal thermal stress (e.g., clinician's cold challenge testing, exercise, environment, etc.) or nonthermal stimuli (e.g., disease, injury, medications, etc.). When properly assessed, skin temperature can provide researchers, scientists, and physicians with valuable information about the blood flow and thermal regulation of organs and tissues (see Example 21.6.1 to Example 21.6.7).

### 21.6.1 Efficiency of Heat Transport in the Skin of the Hand (Example 21.1)

The AVA are specialized vascular structures within acral regions. At normal body temperature, sympathetic vasoconstrictor nerves keep these anastomoses closed. However, when the body becomes overheated, sympathetic discharge is greatly reduced so that the anastomoses dilate allowing large quantities of warm blood to flow into the subcutaneous venous plexus, thereby promoting heat loss from the body (Figure 21.1a). In thermal physiology, hands and feet are well recognized as effective thermal windows. By controlling the amount of blood perfusing through these extremities, the temperature of the skin surface can change over a wide range of temperatures. It is at such peripheral sites that the effect of changes in blood flow, and therefore skin temperature are most clearly discernable.

The following example demonstrates how efficient skin blood flow in the hand is dissipating a large incoming radiant heat load. The radiant heat load was provided by a Hydrosun<sup>®</sup> type 501 water-filtered infrared-A (wIRA) irradiator. The Hydrosun<sup>®</sup> allows a local regional heating of skin tissue with a higher penetration depth than that of conventional IR therapy. The unique principle of operation involves the use of a hermetically sealed water filter in the radiation path to absorb those IR wavelengths emitted by conventional IR lamps which would otherwise harm the skin (OH-group at 0.94, 1.18, 1.38, and 1.87  $\mu\text{m}$ ). The total effective radiation from the Hydrosun<sup>®</sup> lamp was 400  $\text{mW}/\text{cm}^2$ , which is about three times the intensity of the IR-A radiation from the sun. Throughout the time course of the experiment (Figure 21.1a), sequential digital IR-thermal images were taken every 2 sec. With the image analysis software, five points within the radiation field of each image were selected for temperature measurement and used to construct temperature curves shown in Figure 21.1b.

In the experiment (Figure 21.1b) a rubber mat with an emissivity close to 1.0 was irradiated with the Hydrosun<sup>®</sup> wIRA lamp for a period of 25 min at a standard distance of 25 cm. At this distance the circular irradiation field had a diameter of about 16 cm. Since the rubber material has a high emissivity it rapidly absorbs heat from the lamp. As can be seen from the time course of the five temperature curves in Figure 21.2 (five fixed measuring points within the radiation field), the center of the irradiated rubber mat rapidly reached temperatures over 90°C during the first 10 min of irradiation. After the first 10 min of irradiation, the hand of a healthy 54-year-old male subject was abruptly placed on the irradiated rubber mat and kept there for a further 10 min, before being removed. When the hand was placed onto the irradiation field, three of the five fixed temperature-measuring sites now measured skin temperature on the dorsal skin surface. Based on the temperature curves in Figure 21.1b, skin temperature on the surface of the hand directed toward the irradiator never rose higher than 40°C, while the two remaining temperature-measuring points on the rubber mat remained at their original high values. The patient suffered no thermal discomfort from placing his hand on the 'hot' rubber mat, even though the temperature of the center of the rubber mat was more than 90°C before the hand was placed on it. This was presumably due to a combination of the low heat capacity of the rubber material combined with a high rate of skin blood flow that is capable of rapidly dissipating heat. The visual data created from the IR-thermal images coupled with the temperature curves which were calculated from sequential IR-thermal images clearly demonstrates the large heat transporting capacity of the skin.

### 21.6.2 Effect of a Reduced Blood Flow (Example 21.2)

During exposure to cold, heat loss from the extremities is minimized by reducing blood flow (vasoconstriction). In cool environments, this vasomotor tone results in a heterogeneous distribution of skin surface temperatures; while in a warm environment the skin surface becomes more homogeneous (see Figure 21.2a). The importance of the integrity of blood flow in a limb as a whole can also be demonstrated at room temperature by totally cutting off the blood supply to the limb with the aid of a pressure cuff. This is demonstrated in the experiment shown in Figure 21.2b. In this experiment, skin surface on the back of the left hand of a 60-year-old healthy male subject was irradiated for a 10-min period with a wIRA lamp (see description in Section 21.6.1). The fingers were not heated. The heating was repeated twice. In the upper panel (Figure 21.2b) intact blood supply is demonstrated. In the lower panel (Figure 21.2b),

**FIGURE 21.1** (See color insert following, page 29-16.) (a) A Thermogram of a healthy 52-year-old male subject in a cold environment (ca. 15°C; left panel) and in a warm environment (ca. 25°C; right panel). In the cold environment arteriovenous anastomoses in the nose and the auricle region of the ears are closed, resulting in low skin temperatures at these sites. Also note reduced blood flow in the cheeks but not on the forehead, where the blood vessels in the skin are unable to vasoconstrict. (b) Efficiency of skin blood flow as a heat transporter. The photograph in the upper left panel shows a rubber mat being heated with a water-filtered infrared-A irradiator at high intensity (400 mW/cm<sup>2</sup>) for a period of 20 min. In the lower panel the time course of surface temperature of the mat at five selected spots as measured by an IR-camera is given. During the last 10 min of the 20-min heating period, the left hand of a healthy 54-year-old male subject was placed on the mat. Note that skin surface temperature of the hand remains below 39°C.

	Anterior torso	Posterior torso	Anterior arms	Posterior arms	Palmer hands	Dorsal hands
Cool 20°C	5.0	5.1	6.3	4.5	5.2	4.0
Warm 41°C	3.0	3.2	3.2	3.6	4.0	3.5

**FIGURE 21.2** (See color insert.) (a) A The thermoregulatory response of the torso when exposed to a cool or warm environment. Note the heterogeneous temperature distribution in the cool environment as opposed to the more homogeneous temperature distribution in the warm environment. Different colors represent different temperatures. One might recognize the difficulty related to choosing one point (thermocouple data) as the reference value in a region.

thermal response to heating of the limb while blood flow was totally restricted using a blood pressure cuff is presented. The time course of the temperature curves shown in the upper panel of Figure 21.2b demonstrates a gradual increase in skin temperature, eventually stabilizing just below 39°C. The finger skin temperature on the heated hand only showed a minor increase during the heating period. When the lamp was switched off the accumulated heat was rapidly dissipated and skin temperature of the heated area returned to the preheating level. In the lower panel the experiment was repeated, but as the heater was turned on, a pressure cuff placed around the upper arm was inflated to above systolic pressure to totally cut off blood supply to the arm. As can be seen, the rate of rise of skin temperature over the heated skin area was quite rapid, soon reaching a level deemed to be uncomfortably hot, after which the heater was turned off (at this stage the pressure cuff was still inflated). During the heating period finger skin temperature on the same hand steadily decreased (i.e., the fingers were passively cooling due to lack of circulation). After the heater was turned off the temperature of the back of the left hand also began to decrease indicating a passive cooling. When the pressure cuff was reopened and blood flow to the arm reestablished, the rate of cooling on the back of the hand increased (active cooling) and the skin temperature of the cooled fingers also rapidly returned to normal.

While the same result could have been gained by using other methods to measure skin temperature, such as thermocouples, the visual effect gained by using IR thermography provides much more information

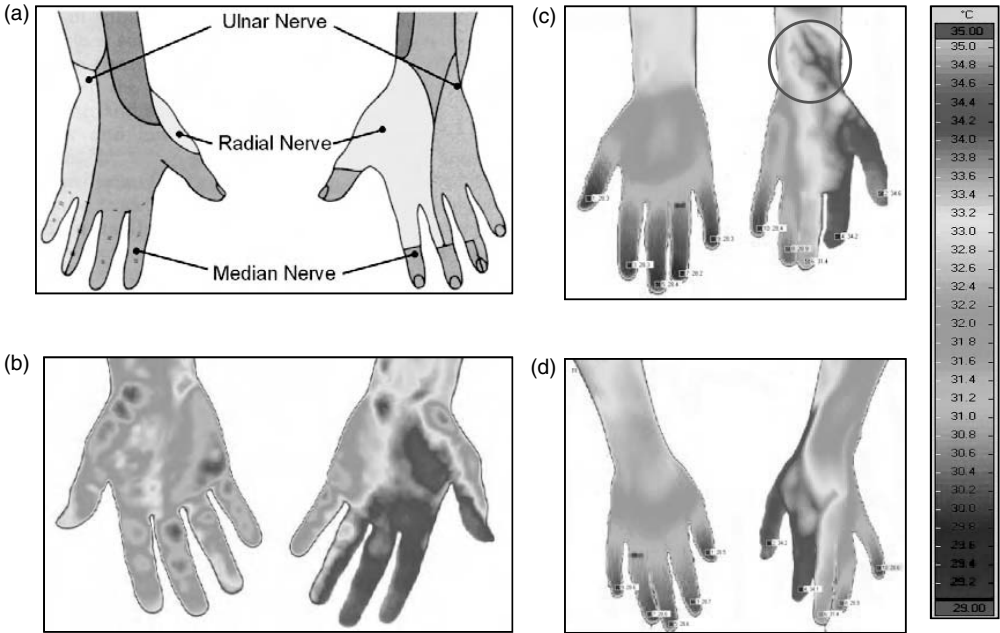

**FIGURE 21.2** (Continued.) (b) Skin heating with and without intact circulation in a 65-year-old healthy male subject. The two panels on the right show the time course of 6 selected measuring sites (4 spot measurements and 2 area measurements) of skin temperatures as determined by IR-thermography before, during, and after a period in which the skin surface on the back of the left hand was heated with a water-filtered infrared-A irradiator at high intensity ( $400 \text{ mW/cm}^2$ ) in two separate experiments. The results shown in the upper right panel were performed under a situation with a normal intact blood circulation, while the results shown in the lower left panel were made during total occlusion of circulation in the right arm by means of an inflated pressure cuff placed around the upper arm. The time of occlusion is indicated. The IR-thermogram on the left was taken just prior to the end of the heating period in the experiment described in the upper panel. The location of the temperature measurement sites on the hand (4 spot measurements [Spot 1–Spot 4] and the average temperature within a circle [Area 5 and Area 6]) are indicated on the thermogram.

than a single point measurement. Various points or areas of interest can be investigated during and after the experimental procedures. Modern digital image processing software provides endless possibilities, especially with systems allowing the recording of sequential IR-images. Today modern fire-wire technology permits one to record IR-images at very high frequencies (100 Hz and greater).

### 21.6.3 Median Nerve Block in the Hand (Example 21.3)

The nervous supply to the hand is via three main nerves: radial, ulnar, and median nerve. The approximate distribution of the sensory innervation by these nerves is shown in Figure 21.3a. With a sudden removal (or disruption) of the sympathetic discharge to one of the main nerves, a maximal vasodilatation of blood vessels in the area supplied by the nerve is observed. Such a vasodilatation will result in a significant increase in skin blood flow to that area and therefore in a rise in skin temperature. The IR-thermogram in Figure 21.3b shows such a response. The subject is a 40-year-old female suffering from excessive sweating in the palms of her hands, a condition known as hyperhidrosis palmaris. Excessive sweating causes cooling of the skin surface. The blue color in Figure 21.3b represents areas of excessive sweating as well as areas of lowest skin temperature. Hyperhidrosis palmaris is treated by subcutaneous injections of Botulinum Toxin. The skin in the palm of the hand is very sensitive and anesthesia is therefore required. A very effective way to provide adequate anesthesia is the median nerve block. At the level of the wrist, a local anesthetic is injected around the median nerve and blocks the nervous activity in the median nerve.

**FIGURE 21.3** (See color insert.) (a) The distribution of cutaneous nerves to the hand. (b) IR-thermogram of a 40-year-old female patient following a successful nerve block of the left median nerve. (c) and (d) IR-thermograms of the hands of a 36-year-old female patient whose left wrist (middle of the red circle) was punctured with a sharp object resulting in partial nerve damage (motor and sensory loss). The strong vasodilatory response resulting from partially severed nerves can be easily seen.

The resulting increase in skin temperature on the palmar side of the left hand after such an injection is clearly seen in Figure 21.3b. One sees that part of the thumb and half of the fourth finger show no increase in temperature, closely matching the predicted area of distribution for this nerve in Figure 21.3a. Although a median nerve block was applied to the right hand, neither vasodilatation nor a change in skin temperature was seen. The Botulinum Toxin injections on this side were painful. The placement of the anesthetic was therefore incorrect, and as a result, normal nervous activity in the right hand was observed. In Figure 21.3c,d, the thermograms show the hands of a 36-year-old female patient. Her left wrist (middle of the red circle) was punctured with a sharp object, resulting in partial nerve damage. The strong vasodilatory response, due to the nerve damage, results in an increased skin temperature as shown in Figure 21.3d.

The diagnosis of acute nerve damage can be a challenge for a surgeon. In the acute situation, pain makes a proper physical examination often impossible. To evaluate the extent of the nerve injury, cooperation of the patient is necessary and the use of local anesthesia can mask the extent of the injury. IR-thermography proves to be a helpful, noninvasive diagnostic tool by visualizing changes in skin temperature and, indirectly blood flow to the skin, due to the nerve injury.

**21.6.4 Infrared-Thermography and Laser Doppler Mapping of Skin Blood Flow (Example 21.4)**

As mentioned in the introduction above, one of the drawbacks of using IR-thermography to indirectly indicate changes in skin blood flow is being able to decide, for example, if an increase in skin temperature is due to a parallel increase in skin blood flow. One way to verify whether observed skin temperature changes are related to changes in skin blood flow is to combine IR-thermography with a more direct measurement technique of skin blood flow. Laser Doppler can ascertain the direction of skin blood flow

**FIGURE 21.4** (See color insert.) IR-thermograms, temperature profiles, scanning laser Doppler scans (SLD), and blood flow profiles (perfusion units PU) of the abdominal area of a 44-year-old healthy female subject before (a), immediately after (b), and 5 min (c), 10 min (d) and 20 min (e) after a 20 min heating of the right side of the abdomen with a water-filtered infrared-A irradiation lamp. The blue horizontal lines in the IR-thermograms indicate the position of the temperature profiles. The red horizontal lines in the SLD scans indicate the position of the blood flow profiles. In IR-thermogram (b) the white color indicates skin temperatures greater than 36°C.

but these measurements are restricted to small surfaces and blood flow is not quantified but reported as changes in Doppler units or volts [45]. With IR-thermography rapid changes in skin temperature over a large area can be easily measured. Laser-Doppler mapping involves a scanning technique using a lower power laser beam in a raster pattern and requires time to complete a scan (up to minutes depending on the size of the scanned area). During the time it takes to complete a scan it is possible that the skin blood flow has changed in the skin area examined at the start compared to the skin area being examined at the end of each scan. This is most likely to happen in dynamic situations where skin blood flow is rapidly changing. Despite this drawback, the use of IR-thermography and laser Doppler mapping can provide a complimentary investigative view of this dynamic process.

In Figure 21.4, both IR-thermography and scanning laser Doppler mapping have been simultaneously used to examine a healthy 44-year-old female subject. In this experiment the subject was submitted to a 20 min heating of the right side of the abdomen using a water filtered IR-A irradiation lamp (see Section 21.6.1). During the period of heating, the left side of the abdomen was covered with a drape to prevent this side of the body from being heated. At predetermined intervals prior to, during, and

**FIGURE 21.5** (See color insert.) Abdominal cooling in a 32-year-old female patient prior to breast reconstruction surgery. In this procedure skin and fat tissue from the abdominal area was used to reconstruct a new breast. The localization of suitable perforating vessels for reconnection to the mammary artery is an important part of the surgical procedure. In this sequence of thermograms the patient was first subjected to a mild cooling of the abdominal skin (2 min fan cooling). IR-thermograms of the skin over the entire abdominal area were taken prior to, immediately after, and at various time intervals during the recovery period following the cooling period. To help highlight the perforating vessels, an outline function has been employed in which all skin areas having a temperature greater than 32.5°C are enclosed in solid lines.

after the heating period both IR-thermal images and laser Doppler mapping images were recorded, the latter with a MoorLDI™ laser Doppler imager (LDI-1), Moor Instruments, England. As can be seen in Figure 21.5, the wIRA heating lamp causes a large increase in skin temperature on the irradiated side of the abdomen. After the end of the heating period, the temperature of the heated area gradually decreases. These changes nicely correspond with the laser Doppler mapping images. A semi quantitative value of blood flow (perfusion units) for each LDI image was also calculated (right panels in Figure 21.5). Each blood flow profile corresponds well with their respective temperature profiles.

### 21.6.5 Use of Dynamic IR-Thermography to Highlight Perforating Vessels (Example 21.5)

The procedure of dynamic thermography involves promoting changes in skin blood flow by local heating or cooling. In the example shown in Figure 21.5, a mild cooling (2 min period of fan cooling) of the skin overlying the abdominal area of a 36-year-old female patient prior to undergoing breast reconstruction surgery was performed in order to highlight perforating blood vessels [41]. These blood vessels originate in deeper lying tissue and course their way toward the skin surface, although they may not necessarily reach the skin surface. By invoking a local cooling, a temporary vasoconstrictor response is initiated in skin blood vessels. Blood flow in the perforating blood vessels is little affected and following the end of the cooling period they rapidly contribute to the skin rewarming. During the rewarming process the localization of the “hot-spots” caused by these perforating vessels becomes more diffuse as heat from them spreads into neighboring tissue. This technique allows one to more easily identify so-called perforator vessels of the

medial and lateral branches of the deep inferior epigastric artery, one or more of which will be selected for reconnection to the internal mammary artery (the usual recipient vessel) during reconstruction of a new breast from this abdominal tissue.

### 21.6.6 Reperfusion of Transplanted Tissue (Example 21.6)

With the development of microvascular surgery, it has become possible to connect (anastomose) blood vessels with a diameter as small as 0.5 mm to each other. Transplantation of tissue from one place to another place in the same patient (autologous transplantation) or from one individual to another (allogous transplantation) has become daily practice in medicine. The technique requires high surgical skills. During the operation, blood supply to the transplant is completely severed and the blood vessels to the transplant are later connected to recipient vessels. These recipient blood vessels will supply blood to the transplant at the new site. Kidney transplantation is a well-known example of allogous transplantation. Here, a patient with a nonfunctional kidney receives a donor kidney to provide normal renal function. Nowadays, autologous tissue transplantation is an integrated part in trauma surgery and cancer surgery. The successful reperfusion of the transplant is obviously essential for its survival. A nonsuccessful operation causes psychological stress for the patient and is indeed an inefficient use of resources stress. IR-thermography provides an ideal noninvasive and rapid method for monitoring the reperfusion status of transplanted tissue.

Autologous breast reconstruction is a critical part of the overall care plan for patients faced with a diagnosis of breast cancer and a plan that includes removal of the breast. The deep inferior epigastric perforator (DIEP) flap is the state of the art in autologous breast reconstruction today. The technique uses skin and fatty tissue from the lower abdomen for reconstruction of a new breast (Figure 21.6). The fatty tissue and skin on the lower abdomen are supplied by many blood vessels. By using this tissue as a DIEP flap in autologous breast reconstruction, the blood supply to this tissue is reduced to one single artery and veins, each with a diameter of 1.0 to 1.5 mm. A critical period during the operative procedure is the connection (anastomosing) of the flap to the recipient vessels. The blood vessels of the DIEP flap are anastomosed to the internal mammary vessels to provide blood supply to the flap. Blood circulation to the newly reconstructed breast is dependent on the viability of the microvascular anastomosis. The series of IR-thermograms shown in Figure 21.6 were taken at various time intervals after reestablishing the blood supply to the flap in a patient undergoing autologous breast reconstruction with a DIEP flap.

During the operation, there is a period (ca. 50 min) with no blood supply to the dissected flap, and as a result, it cools down. The rate and pattern of rewarming of the flap after anastomoses to the recipient vessels provides the surgeon with important information on the blood circulation in the transplanted flap. With a successful and adequate outcome of the anastomosis, the rewarming response was found to be rapid and well distributed (Figure 21.6). A poor rewarming response often made an extra venous anastomosis necessary to improve venous drainage (the most common problem). In such cases, IR-thermography provides an excellent method to quickly verify improvement in the blood flow status in the flap. In addition, in the days following surgery, examination of the skin temperatures using IR-thermography of the newly reconstructed breast was found to be a quick and easy way to monitor its blood flow status. The peripheral areas of the new breast can suffer from diminished blood circulation. Improvement in blood circulation could be seen during post surgery.

### 21.6.7 Sports Medicine Injury (Example 21.7)

Thermal images of an injury sustained by an 18-year-old American football player after a helmet impacted the superior portion of his right shoulder. X-ray and MRI immediately post game showed no structural damage. IR images were taken 12 h post injury in a controlled environment (22°C, 30% rh, after 20 min equilibration). Upon examination, the athlete was unable to lift his right arm above shoulder level. Note the disruption in the thermal pattern in the right side torso view (T4 spinal region on left side of image)

**FIGURE 21.6** (See color insert.) Infrared thermal images of an abdominal skin flap during breast reconstruction surgery. The sequence of IR-thermal images demonstrates the return of heat to the excised skin flap following reestablishing its blood supply (anastomizing of a mammary artery and vein to a single branch of the deep inferior epigastric artery and a concomitant vein). Prior to this procedure the excised skin flap had been without a blood supply for about 50 min and consequently cooled down. The photograph in the upper left panel shows the skin flap in position on the chest wall prior to being shaped into a new breast.

and the very cold temperatures and pattern extending down the left arm. After 3 weeks of rehabilitation, the weakness experienced in the shoulder and arm was resolved. IR imaging confirmed a return to normal symmetrical thermal pattern in the back torso and warmer arm temperatures.

### 21.6.8 Conclusions

As pointed out in the introduction to this section the main objective of this article is to try and persuade those who are not familiar with IR-thermography that this technology can provide objective data, which makes clinical sense. The reader has to be aware that the examples presented above only represent a tiny fraction of the possibilities that this technology provides. It is important to realize that an IR-thermal image of a skin area under examination will more often not provide the examiner with a satisfactory result. It is important to keep in mind that blood flow is a very dynamic event and in many situations useful clinical information can only be obtained by manipulating skin blood flow, for example by local cooling. Thus, the need to have a basic understanding of the physiological mechanisms behind the control of skin blood flow cannot be overemphasized. One also has to realize that this technology should be thought of as an aid to making a clinical diagnosis and in many cases should, if possible, be combined with other complementary techniques. For example, IR-thermography does not have the ability to pinpoint the location of a tumor in the breast. Consequently, IR-thermography's role is in addition to mammography, ultrasound and physical examination, not in lieu of. IR-thermography does not replace mammography and mammography does not replace IR-thermography, the tests complement each other.

FIGURE 21.7 (See color insert.) An American football player who suffered a helmet impact to the right shoulder (left side of image). The athlete was unable to flex his arm above shoulder level. Note the asymmetrical torso pattern in the posterior torso.

## Acknowledgments

Examples of IR images from patients and volunteers (Figure 21.1, Figure 21.2b, Figure 21.3 to Figure 21.7) from the Department of Medical Physiology, Faculty of Medicine, University of Tromsø, Norway and the Department of Clinical Physiology, Hillerød Hospital, Hillerød, Denmark. The IR images in these examples were taken using two different IR-cameras: A Nikon Laird S270 cooled camera and a FLIR ThermoCAM<sup>®</sup> PM695 uncooled bolometer. The respective image analysis software used was ThermoCAM researcher ver. 2.1 and PicWin-IRIS, (EBS Systemtechnik GmbH, Munich, Germany). The studies described in Example 21.1 and Example 21.2 were carried out at the Department of Clinical Physiology, Hillerød Hospital, Hillerød, Denmark in collaboration with consultant Dr Stig Pors Nielsen. The assistance of Master student Lise Bøe Setså in the studies described in Example 21.5 and Example 21.6 is also acknowledged. Examples of IR images (Figure 21.2a and Figure 21.8) come from the Thermal Lab,

Auburn University, Alabama, United States, utilizing a Computerized Thermal Imager 2000. We would like to acknowledge the assistance of JohnEric Smith and Estevam Strecker in these projects.

### 22.1 Introduction

---

Static infrared (IR) thermal imaging has a number of attractive properties for its practical applications in industry and medicine. The technique is noninvasive and harmless as there is no direct contact of the diagnostic tool to an object under test, the data acquisition is simple and the equipment is transportable and well adapted to mass screening applications. There are also some fundamental limitations concerning this technique. Only processes characterized by changes in temperature distribution on external surfaces

directly accessible by an IR camera can be observed. The absolute value of temperature measurement is usually not very accurate due to generally limited knowledge of the emission coefficient. Many harmful processes are not inducing any changes in surface temperature, for example, in industrial applications material corrosion or cracks are usually not visible in IR thermographs, in medicine in mammography inspection a cyst may mask cancer, etc. For such cases active dynamic thermal imaging methods with sources of external excitations are helpful. Therefore the nondestructive evaluation (NDE) of materials using active dynamic thermal IR-imaging is extensively studied; see, for example, proceedings of QIRT [1]. The method is already well developed in some of industrial applications but in medicine this technique is almost unknown.

Active dynamic thermal (ADT) IR-imaging, known in industry either as *infrared-nondestructive testing* (IR-NDT), or as thermographic nondestructive testing (TNDT or just NDT), is under intensive development during at least the last 20 years [1,2]. The concept of material testing by active thermography is based on delivery of external energy to a specimen and observation of the thermal response. In ADT imaging only thermal transients are studied. Such approach allows visualization of material subsurface abnormalities or failures and has already gained high recognition in technical applications [1,2]. In medicine it was applied probably for the first time also around 20 years ago [3,4]. Microwave excitation was applied to evidence breast cancer. Unfortunately, after early experiments the research was suspended, probably due to poor control of microwave energy dissipation. Again some proposals to use ADT in medicine have been published at the end of the last years of the 20th century [5–7].

The visualization of affected regions needs some extra efforts therefore the role and practical importance of the use of synthetic pictures in ADT for medical applications should be underlined [8–10]. In this case equivalent thermal model parameters are defined and calculated for objective quantitative data visualization and evaluation.

Potential role of medical applications of ADT is clearly visible from experiments on phantoms, and *in vivo* on animals as well as in clinical applications [11,12].

### 22.1.1 Thermal Tomography

Another concept based on ADT is *thermal tomography* (TT). Vavilov et al. [13–15] dealing with IR-NDT, proposed this term almost 20 years ago. Even today, the concept is not new this modality may be regarded as being still at the early development stage in technical applications, especially taking into account the limited number of practical applications published up to now. The first proposals to apply the concept of thermal tomography in medicine are just under intensive development in the Department of Biomedical Engineering TUG [16–18]. The main differences comparing TT to simple ADT arise due to necessity of advanced reconstruction procedures applied for determination of internal structure of tested objects.

Tomography is known in medical diagnostics as the most advanced technology for visualization of tested object internal structures. X-rays — CT (computed tomography), NMR — MRI (nuclear magnetic resonance imaging), US — ultrasound imaging, SPECT (single-photon emission computed tomography), PET (positron-emission tomography) are the modalities of already established position in medical diagnostics. There are three additional tomography modalities, still in the phase of intensive research and development — optical tomography (OT), electroimpedance tomography (EIT), and TT. Here we concentrate our notice on ADT and TT. The aim of this chapter is discussion of potential applications of the both modalities in medical diagnostics and analysis of existing limitations.

General concept of tomography requires collection of data received in so-called projections — measurements performed for a specific direction of applied excitation; data from all projections form a scan. Having a model of a tested object the inverse problem is solved showing internal structure of the object. In the oldest tomographic modality — CT — the measurement procedure requires irradiation of a tested object from different directions (projections), all possible projections giving one scan. Then, basing on realistic model of a tested object, a reconstruction procedure based on solving the inverse problem allows

visualization of external structure of the object. In early systems, a 2D picture of internal organs was shown; nowadays more complex acquisition systems allow visualization of 3D cases. More or less similar procedures are applied in all other tomography modalities, including TT, OT, and EIT. The main advantages of TT, OT, and EIT technologies are fully safe interaction with tested objects (organisms) and relatively low cost of instrumentation.

The concept and problems of validity in medical diagnostics of ADT imaging as well as of TT are here discussed. In both cases practically the same instrumentation is applied and only the data treatment and object reconstruction differs. Also, the sources of errors influencing quality of measurements and limiting accuracy of reconstruction data are the same. Main limitations are due to the necessity of using proper thermal models of living tissues, which are influenced by physiological processes from one side and are not very accurate due to hardly controlled experiment conditions from the other side.

The main element allowing quantitative evaluation of tested objects is the use of realistic thermal equivalent models. The measurement procedure requires use of heat sources, which should be applied to the object under test (OUT). Thermal response at the surface of OUT to external excitation is recorded using IR camera. Usually the natural recovery to initial conditions gives reliable data for further analysis. The dynamic response recorded as a series of IR pictures allows reconstruction of properties of the OUT equivalent thermal model. Either thermal properties of the model elements (for defined structure of OUT) or the internal structure (for known material thermal properties) may be determined and recognized. The main problem is correlation of thermal and physiological properties of living tissues, which may strongly differ for *ex vivo* and *in vivo* data. Practical measurement results from phantoms and *in vivo* animal experiments as well as from clinical applications of ADT performed in the Department of Biomedical Engineering Gdansk University of Technology (TUG), Poland and in co-operating clinics of the Medical University of Gdansk are taken into account for illustration of this chapter. The studies in this field are concentrated on applications of burns, skin transplants, cancer visualization, and open-heart surgery, evaluation and diagnostics [19–26].

In following subchapters all elements of the ADT and TT procedures are described. First, thermal tissue properties are defined. Then basic elements of thermal model construction are described. Following is description of the experiment of active dynamic thermography based on OUT excitation (pulse) and infrared recording. Finally the procedures of model identification are described basing on phantom and *in vivo* experiments. Some clinical applications illustrate practical value of the described modalities.

## 22.2 Thermal Properties of Biological Tissues

---

What is the basic difference between IR-thermography (IRT) and ADT and TT?

In IRT, main information is the absolute value of temperature,  $T$ , and distribution of thermal fields,  $T(x, y)$ . Therefore regions of high temperature (hot spots) or low temperature (cold spots) are determined giving usually data of important diagnostic value. Unfortunately the accuracy of temperature measurements is limited. It is mainly due to limited accuracy of IR cameras; due to limited knowledge of the emission coefficient, as individual features of living tissues may be strongly diversified; finally due to hardly controlled conditions of the environment, what may strongly influence temperature distribution at the surface and its absolute values. Additionally surface temperature does not always properly reflects complicated processes, which may exist underneath or in the tissue bulk or which may be masked by fat or other biological structures.

In ADT and TT basic thermal properties of tissues are quantitatively determined; the absolute value of temperature practically is not interesting. Only thermal flows are important. We ask the question — how fast are thermal processes? In ADT, specific equivalent parameters are defined and visualized. In TT directly either spatial distribution of thermal conductivity is of major importance or for known tissue properties the geometry of the structure is determined.

Basic thermal properties (Figures of Merit) of materials and tissues important in ADT and in TT are following:

- $k$  — Thermal conductivity — ( $\text{W m}^{-1} \text{K}^{-1}$ ), it describes ability of a material (tissue) to conduct heat in the steady state conditions
- $c_p$  — Specific heat — ( $\text{J kg}^{-1} \text{K}^{-1}$ ), describes ability of a material to store the heat energy. It is defined by the amount of heat energy necessary to raise the temperature of a unit mass by 1 K
- $\rho$  — Density of material — ( $\text{kg m}^{-3}$ )
- $\rho c_p$  — Volumetric specific heat — ( $\text{J m}^{-3} \text{K}^{-1}$ )
- $\alpha$  — Thermal diffusivity — ( $\text{m}^2 \text{sec}^{-1}$ ); is defined as

$$\alpha = \frac{k}{\rho \cdot c_p} \quad (22.1)$$

Volumetric specific heat and thermal conductivity are responsible for thermal transients described by the equation

$$\frac{\partial T}{\partial t} = \alpha \nabla^2 T \quad (22.2)$$

For one directional heat flow (what describes the case of infinite plate structures composed of uniform layers and uniformly excited at the surface) this may be rewritten in the form:

$$\frac{\partial T}{\partial t} = \frac{k}{\rho \cdot c_p} \cdot \frac{\partial^2 T}{\partial x^2} \quad (22.3)$$

Thermal diffusivity describes heat flow and is equivalent to the reciprocal of the time constant  $\tau$  describing the electrical RC circuit:

$$\alpha = \frac{k}{\rho \cdot c_p} \leftrightarrow \frac{1}{\tau} = \frac{1}{RC} \quad (22.4)$$

Basing on this analogy, materials are frequently described by equivalent thermal model composed of thermal resistivity  $R_{th}$  and thermal capacity  $C_{th}$ , which are responsible for the value of the thermal time constant,  $\tau_{th}$ ,

$$\tau_{th} = R_{th} C_{th} \quad (22.5)$$

Those are the most frequently used equivalent parameters. Determination of such parameters is easy basing on measurements of thermal transients and using fitting procedures for determination of the applied model parameters.

Additionally one may define thermal inertia as  $k \cdot \rho \cdot c_p$ .

Useful may be also introducing the definition of thermal effusivity  $\beta$ , defined as the root-square of the thermal inertia — ( $\text{J m}^{-2} \text{K}^{-1} \text{sec}^{-1/2}$ ) or ( $\text{W sec}^{1/2} \text{m}^{-2} \text{K}^{-1}$ ).

$$\beta^2 = k \cdot \rho \cdot c_p \quad (22.6)$$

Importance of IRT and ADT/TT in medical diagnostics is complementary. Regions of abnormal vascularization are detected in IRT as *hot spots* in the cases of intensive metabolic processes or as *cold spots* for regions of affected vascularization or necrosis. The same places may represent higher or lower thermal conductivity, but this is not a rule. Thermal properties of tissues may differ significantly depending on the vascularization, physical structure, water content, and so on. Knowledge of thermal properties and geometry of tested objects may be used in medical diagnostics if correlation of thermal properties and specific physiological features are known. Important is character of the data allowing objective quantitative description of tissues or organs.

The main advantage of thermal tissue parameter characterization comparing to absolute temperature measurements is relatively low dependence on external conditions, for example, ambient temperature, what usually is of a great importance in IRT. The main disadvantage is still limited knowledge of thermal tissue properties and very complicated structure of biological organs. Although the first results of thermal tissue properties have been published at the end of 19th century, the main data, still broadly cited, were collected around 30 years ago [27–30]. Unfortunately, literature data of thermal tissue properties should be treated as not very reliable, because measurement conditions are not always known [31], *in vivo* and *ex vivo* data are mixed, etc. Table 22.1 illustrates this problem. Detailed description of measurement methods of biological tissue thermal parameters is given in References 18, 31, and 32.

In Table 22.2 basic thermal tissue properties — mean values of data given by different studies and for different tissues taken *in vitro* at 37°C — are collected [18].

It has to be underlined that thermal tissue properties are temperature dependent (typically around 0.2–1 %/°C). In most of ADT and TT measurements this effect may be neglected as being not significant for data interpretation, as possible temperature differences are usually limited. The differences of temperature in *in vivo* experiments may be usually neglected as not important at all. Also there is a strong influence of water content and blood perfusion, see, for example, results of Valvano et al., 1985 in Reference 33. Usually effective thermal conductivity and diffusivity are applied to overcome this problem in modeling of thermal processes. Additionally, in subtle analysis one should remember that some tissues might be anisotropic [18,31].

For mixture of  $N$  substances, each characterized by thermal conductivity  $k_1, \dots, k_N$ , the effective thermal conductivity is the mean value of the volumetric content of components:

$$k_{tk} = \frac{\sum_{i=1}^N k_i \cdot V_i}{\sum_{i=1}^N V_i} = \rho_{tk} \sum_{i=1}^N k_i \frac{m_i}{m_{tk}} \cdot \frac{1}{\rho_i} \tag{22.7}$$

where the index  $tk$  concerns all tissue, and the index  $i$  —  $i$ th component. Analogically, one may calculate effective specific heat either as the mean value of mass components

$$c_{wtk} = \frac{\sum_{i=1}^N c_{wi} \cdot m_i}{\sum_{i=1}^N m_i} \tag{22.8}$$

or as the mean value of volumetric components

$$\rho_{tk} c_{wtk} = \frac{\sum_{i=1}^N \rho_i c_{wi} \cdot V_i}{\sum_{i=1}^N V_i} \tag{22.9}$$

Marks and Burton [34] propose a thermal model, composed of three components — water, fat, and proteins — using the values collected in the Table 22.3. Though, it was suggested that more realistic values of thermal conductivity are given by Bowman [18,28].

## 22.3 Thermal Models and Equivalent/Synthetic Parameters

Basic analysis of existing thermal processes in correlation with physiological processes is necessary to understand significance of thermal flows in medical diagnostics. Thermal models are very useful to study such problems. It should be underlined that ADT and TT are based on analysis of thermal models of tested objects. Solution of the so-called direct problem while external excitation (determination of temperature distribution in time and space for assumed boundary conditions and known model parameters) involves simulation of temperature distribution in defined object under test. It allows study on thermal tomography concept, simulation of heat exchange and flows using optimal excitation methods, analysis of theoretical, and practical limitations of proposed methods, etc.

Direct problems may be properly solved only for realistic thermal models. Having such a model, one can compare the results of experiments and can try to solve the reverse problem. This responds to the question — what is the distribution of thermal properties in the internal structure of a human body? Such knowledge may be directly used in clinical diagnostics if the correlation of thermal and physiological properties is high.

In biologic applications solution of the direct problem is basic to see relationship between excitation and temperature distribution at the surface of a tested object, what is a measurable quantity. This requires solution of the heat flow in 3D space. Equation 22.10, representing the general parabolic heat flow [35] describes this problem mathematically:

$$\operatorname{div}(k \cdot \operatorname{grad} T) - c_p \rho \frac{\partial T}{\partial t} = -q(P, t) \quad (22.10)$$

where  $T$  is the temperature in K;  $k$  the thermal conductivity in  $\text{W m}^{-1} \text{K}^{-1}$ ,  $c_p$  the specific heat in  $\text{J g}^{-1} \text{K}^{-1}$ ;  $\rho$  the material (tissue) density in  $\text{g m}^{-3}$ ,  $t$  the time in sec, and  $q(P, t)$  is the volumetric density of generating or dissipated power in  $\text{W m}^{-3}$ . For biologic tissues Pennes [36] defined “the biologic heat flow equation”:

$$c_p \rho \frac{\partial T(x, y, z, t)}{\partial t} = k \nabla^2 T(x, y, z, t) + q_b + q_m + q_{ex} \quad (22.11)$$

where  $T(x, y, z, t)$  is the temperature distribution at the moment  $t$ ,  $q_b$  ( $\text{W/m}^3$ ) the heat power density delivered or dissipated by blood,  $q_m$  the heat power density delivered by metabolism, and  $q_{ex}$  is the heat power density delivered by external sources. Solving of this equation, including all processes influencing tissue temperature, is very complicated and analytically even impossible. Generally there are three approaches in analysis and solving of heat transfers and distribution of temperature.

The first one is analytic, usually very simplified description of an object, typically using the Fourier series method. Analytical solutions of heat flows are known only for very simple structures of well-defined shapes, what usually is not the case acceptable for analysis of biological objects. The simplest solution assumes one directional flow of energy, as it is for multilayer, infinite structures, thermally uniformly excited. Distribution of temperature, if several sources exist, may be solved assuming the superposition method.

The second option is the use numerical methods, usually based on finite element method (FEM); to model more complicated structures. There are several commercial software packages broadly known and used for solving problems of heat flows, usually combining a mechanical part, including generator of a model mesh as well as modules solving specific thermal problems, for example References 37 and 38. Also general mathematical programs, as Matlab [39] or Mathematica [40], contain proper tools allowing thermal analysis. FEM methods allow solution of 3D heat flow problems in time. Functional variability of thermal properties and nonlinear parametric description of tested objects may be easily taken into consideration. Again, there are basic limitations concerning the dimension of a problem to be solved (complexity and number of model elements), which should be taken into account from the point of view of the computational costs.

The solution of the Equation 22.10 and Equation 22.11 may be given in the explicit form:

$$T_n^{i+1} = \frac{\Delta t}{\rho c_p V_n} \left[ \sum_m k_{nm} T_m^i + \left( \frac{\rho c_w V_n}{\Delta t} - \sum_m k_{nm} T_m^i \right) + q_n V_n \right] \quad (22.12)$$

or in the implicit form:

$$T_n^{i+1} - T_n^i = \frac{\Delta t}{\rho c_p V_n} \left[ \sum_m k_{nm} (T_m^{i+1} - T_n^i) + q_n V_n \right] \quad (22.13)$$

where  $i$  indicates moment of time,  $\Delta t$  is the time step,  $n$  the position in space (node number),  $V_n$  the volume of the  $n$  node,  $m$  indicates neighboring nodes,  $k_{nm}$  is thermal conductivity between the nodes  $n$  and  $m$ ,  $T_n^i$  the temperature of a node at the beginning of a time step,  $T_n^{i+1}$  the temperature of a node at the end of the time step, and  $q_n$  is the power density representing generation of heat per unit volume at the  $n$ th node. Each node represents a specific part of the modeled structure defined by mass, dimensions, and physical properties. The node is assumed to be thermally uniform and isotropic. Boundary conditions may be assumed discretional, depending on real conditions of experiments to be performed (under analysis). Usually adiabatic or isothermic conditions and a value of excitation power are assumed. The boundary conditions, the value of excitation power as well as individual properties of any node may be modified with time!

In the explicit method the temperature of each node is determined at the end of the time step, taking into account the heat balance based on temperature, heat generation, and thermal properties at the beginning of the time step. Assuming neither proper time step nor model geometry may effect in lack of stable solution or poor accuracy of analysis.

In the implicit method, the increase of temperature in each node is calculated from the heat balance resulting from temperatures, heat generation, and thermal properties during the time step. The solution is stable. The duration of a time step may be modified in the adaptation procedure assuming several conditions, for example, maximum rise of temperature in any of nodes. Increase of iteration steps followed by the need of many possible modifications of parameters during iterations may lead to unacceptable rise of the computation time. Still, the mesh geometry may influence accuracy of analysis.

The numerical modeling is preferable in cases where solution of the direct problem may be sufficient, for example, in analysis of methods of investigation, because it allows easy and accurate modifications of important factors influencing measurements. The forward problem may be solved for any configuration of mesh and tissue as well as excitation parameters. Unfortunately, limited knowledge of living tissue properties is reducing possibility of using simulation methods for reliable *in vivo* case analysis.

The third approach is to build simple equivalent models of tested tissues or organs based on such synthetic parameters as thermal resistivity (conductivity) and thermal capacity. This solution, as the simplest one, seems to be the most useful practically. A medical doctor may accept relatively simple, still reliable description, based on synthetic parameters easily determined for such simple models. As an example, thermal structure of the skin may be represented by three equivalent layers described by the  $R_{th}(1-3)C_{th}(1-3)$  model. Values of such simple model parameters may be relatively easily determined from experimental data using fitting procedures and well correlated to physical phenomena, for example, depth of burns. This is also probably the easiest method to be applied for solving the inverse problem and therefore the best offer for modern computer technology based diagnostic tools. Also, correlation of model parameters coefficients is not as complicated as in the case of the FEM approach.

## 22.4 Measurement Procedures

Study of heat transfer enables quantification of thermo-physical material properties such as thermal diffusivity or conductivity and finally detection of subsurface defects. The main drawback of thermal measurement methods is limitation in number of contact sensors distributed within a tested object or

FIGURE 22.1 Schematic diagram of ADT and TT instrumentation.

FIGURE 22.2 Model-based identification of a tested structure (object).

application of IR-methods of temperature measurements, allowing observation of the surface temperature distribution only, what in both cases results in limited accuracy of analysis.

The ADT and TT are based on IR technology. The general concept of measurements performed in such applications is shown in Figure 22.1. External thermal excitation source (heating or cooling) is applied to a tested object (TO). First, steady state temperature distribution on TO surface is registered using the IR camera. The next step requires thermal excitation application, and registration of temperature transients on the TO surface. The control unit synchronizes the processes of excitation and registration. All data are stored in the data acquisition system (DAS) for further computer analysis.

To allow quantitative evaluation of TO properties, the procedures of both, ADT and TT, are based on determination of thermal models of TO. Typical procedure of model parameter estimation is shown in Figure 22.2. For the measurement structure shown in Figure 22.1 an equivalent model of TO must be assumed (developed and applied in the procedure). In this case usually a simple model, for example, the three layers  $R_{th}(1-3)C_{th}(1-3)$ , is applied. Thermal excitation (from a physical source as well as simulated for the assumed model), applied simultaneously to TO and to its model, results in thermal transients, registered at the surface of TO by the IR camera (applied and simulated for the model). For each pixel, the registered temperature course is identified (typically the least square approximation — LSA and exponential model for thermal transients are applied). The result (measured thermal course) is compared with the simulated transient and if necessary the thermal model is modified to fit to experimental results.

The registration process is illustrated in Figure 22.3. An example for a pulse excitation and registration of temperature only during the recovery phase (in this case — cooling, after heating excitation) is shown.

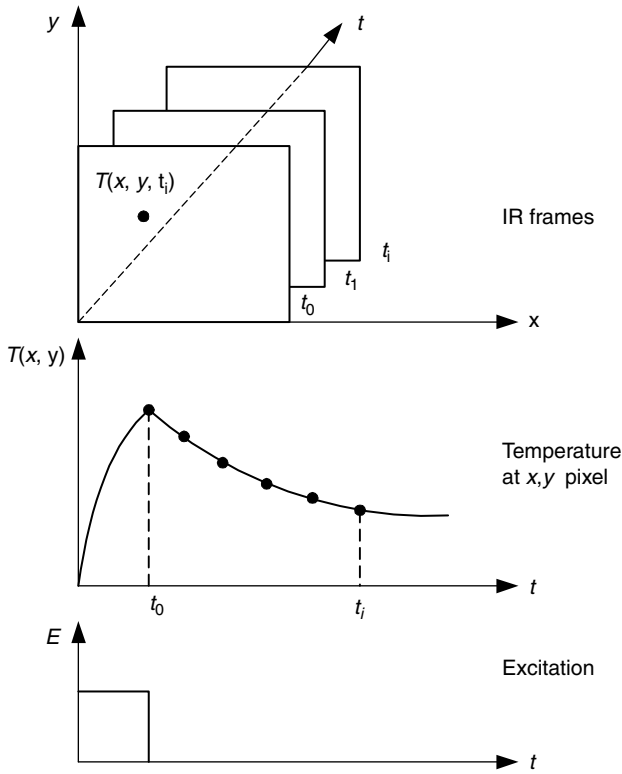

FIGURE 22.3 Registration procedure — after thermal excitation (here heating), a series of IR frames are recorded in controlled moments, starting just at the moment of switching the excitation off; temperature of each pixel is recorded to calculate time constants specific in each pixel.

This is a typical case of practical measurements using optical excitation. Each pixel showing the temperature distribution at the TO surface is represented by an equivalent model, therefore single excitation and registration of transient temperatures at the position  $x, y$  allows identification of the structure *in depth*, resulting in 3D picture of TO.

There are several procedures of nondestructive evaluation of defects by observation of temperature changes of an inspected sample surface using IR-imaging [2]:

1. Continuous heating of a tested object and observation of surface temperature changes during thermal stimulation (step heating, long pulse); the main drawback of the method is limited possibility of quantitative measurements. The information may be similar to classical static thermography with enhancement of specific defects.
2. Sinusoidal heating and synchronized observation of temperature distribution during stimulation (lock-in technique); this is the most accurate NDT-ADT method but not practical in medical applications as the experiment is rather difficult and time consuming.
3. Pulse excitation (e.g., heating using optical excitation, air fan for cooling, etc.) and observation during the heating and/or the cooling phases. Several procedures are possible, as pulsed ADT, multi-frequency binary sequences (MFBS) technique, pulse phase thermography (PPT), and other. The description in the following text is concentrating on a single pulse excitation, because this experiment is relatively simple, fast and of accuracy acceptable in medical applications. The time of excitation may be set short enough to eliminate biofeedback interactions, which are otherwise difficult in interpretation.

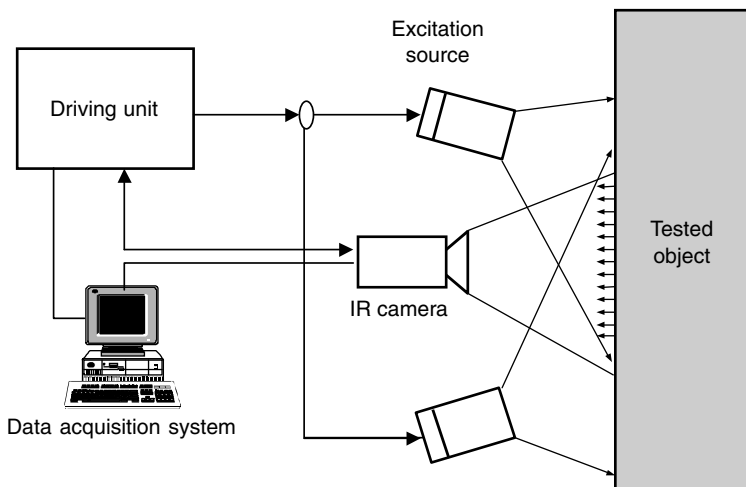

## 22.5 Measurement Equipment

Typical measurement set is shown in Figure 22.4. The main elements of the set are shown: an IR camera; a fast data acquisition system; a set of excitation sources with a synchronized driving unit.

The better are the camera properties the higher accuracy measurements are possible, what is a condition for proper reconstruction of thermal properties of TO. Minimal technical requirements for an IR camera are: repetition rate 30 frames/sec; MRTD better than  $0.1^{\circ}\text{C}$ ; LW — long wavelengths range preferable; FOV dependent on application — typically in clinical conditions measurements taken from around 1 m distance to a patient are advisable. Still application of a cooled FPA camera with higher registration speed and better MRTD would be advisable. SW cameras may be used for other than optical excitations or for analysis of the recovery phase only (time when the excitation is switched off).

Very important is the use of proper excitation sources. Application of optical halogen lamps, laser sources, microwave applicators, even ultrasound generators for heating and air fans or cold sprays for cooling, and some other has been noted [41–44]. As a heating source, an optical or IR lamp, a laser beam, a microwave generator, or an ultrasonic generator can be used. Electromagnetic or mechanical irradiation generated by a source (usually distant) is illuminating a tested object and generating a heating wave proportional to the irradiation energy and to the absorption rate, specific for a tested object material and varying with wavelength of excitation. Microwave irradiation, ultrasonic excitation or electric current flow might generate heat inside a specimen proportional to its dielectric or mechanical properties. For the microwave excitation the main role in the heating process plays the electrical conductivity of a tested object. For the ultrasonic excitation the thermo-elastic effect and mechanical hysteresis are responsible for temperature changes proportional to the applied stress tensor. For the optical irradiation the absorption coefficient is describing the rate of energy converted into heat.

In ADT, the basic information is connected with time dependent reaction of tested structures therefore it is very important to know the switching properties of the heating or cooling sources, especially the raising and the falling time of generated pulses. Dynamic properties of heating or cooling sources must be taken into account during modeling the different shapes of excitation. Some extra measures should be practically adopted, for example, to avoid the interaction between a lamp, which is self-heated during experiments, and a tested object; sometimes a special shutter is needed to assure proper shape of a heating signal. For microwave excitation the applicator must be directly connected to a tested object therefore a time for mechanical removing of an applicator from the heated object to allow thermographic observation is additionally needed what practically eliminates application of such sources in medical applications.

**FIGURE 22.4** Measurement set — tested object is exposed to external thermal excitation; the IR camera, synchronically with excitation records, surface temperature distribution in time.

**TABLE 22.4** Wavelengths and Penetration Depths of the Microwave Source 2.45 GHz for Typical Tissue with Low and High Water Content

Water content	$\lambda$ — In air (cm)	$\lambda$ — In tissue (cm)	$\sigma$ — Tissue conductivity (S/m)	Penetration depth (cm)
High (muscle, skin)	12.2	1.76	2.21	1.70
Low (fat, bones)	12.2	5.21	0.96–2.13	11.2

Source: Duek A.F., *Physical Properties of Tissue*, Academic Press, London, 1990.

There are several conclusions regarding application of different sources of thermal excitation:

1. We are dealing with biological objects; therefore heating should be limited to a safe level, not exceeding 42°C; while cooling temperature of a living tissue should not be lower than 4°C.
2. Thermal excitation should be as uniform as possible; nonuniform excitation results in decrease of accuracy and misinterpretation of measurement data. It is relatively easy to fulfil this condition for optical excitation but very difficult for ultrasonic or microwave methods, even using specially developed applicators.
3. The other important factor is the depth of heat penetration. For different sources of excitation the energy penetration can vary from superficial only absorption to millimeters for some laser beams or even up to a few centimeters for microwave excitation. Ultrasounds are not applicable for biological tissues but of rigid structures only. As an example the data concerning microwave penetration are shown in the Table 22.4. High heat penetration may be very interesting for discrimination of deep regions; unfortunately control of microwave energy absorption practically is impossible being dependent on tissue electrical properties. This feature makes the use of microwave sources in medical applications very problematic.
4. Temperature interactions should be limited to periods not affected by biological feedback; additionally to assure proper data treatment special care should be devoted to fast switching the excitation power on and off. For optical sources mechanical shutters are advisable, as electrical switching is effective in the visible range but also other elements as, for example, housing may be heated to a level influencing sensitive IR camera.
5. Noncontact methods, as optical, seem to be especially appreciated, as septic conditions are easy to be secured.
6. Concluding — optical excitation for heating and air fan for cooling seem to be the best options for daily practice in medical diagnostics.

Even ADT is not so sensitive to external conditions as the classical IRT still there are several conditions to be assured. Generally, patients should be prepared for experiments and all “golden standards” valid for classical thermography here should be also applied [46].

## 22.6 Procedures of Data and Image Processing

Depending on the method of excitation several procedures may be adopted to process the measurement data and then to extract diagnostic information. Here we concentrate only on pulse excitation as is at it is shown in Figure 22.3. Measurements of transients during the heating and the cooling phases allow further use of procedures developed for pulsed thermography (PT), ADT IR-imaging, pulse phase thermography (PPT), and TT. In all four cases, excitation and registration of thermal transients is performed in the same way using IR camera. Visualization data differ as it is expressed respectively by thermal contrast images in PT; thermal time constants in ADT and phase shift images in PPT, finally thermal conductivity distribution in TT.

### 22.6.1 Pulsed Thermography

Pulsed thermography applies calculation of *the maximal thermal contrast index* —  $C(t)$  [2].

$$C(t) = \frac{T_d(t) - T_d(0)}{T_s(t) - T_s(0)} \tag{22.14}$$

where  $T$  is the temperature,  $t$  the time; for  $t = 0$  the sample temperature is maximal, d, s are the subscripts indicating the defect and the sample. With given number of temperature images acquired during PT, the thermal contrast image may be expressed also as

$$C(x, y, t) = \frac{T(x, y, t) - T(x_0, y_0, t)}{T(x_0, y_0, t)} \tag{22.15}$$

where  $x, y$  is the pixel coordinates and  $x_0, y_0$  the pixel coordinates of the reference point in the chosen defect area.

To calculate contrast images, a defect template or a reference point should be defined. In medical applications, it is almost impossible to indicate such templates therefore to overcome this limitation estimation of the behavior of living tissues in PT conditions is possible. As an example, heat transfer caused by blood flow is different in normal and affected (e.g., cancerous) tissues. During the heating process the affected tissues usually are heated more than the normal tissues, what is caused by reduced thermoregulation. Further image processing (segmentation) allows discrimination of so-called *hot spots* and *cold spots* images. Another possibility is to define *the normalized differential PT index* (NDPTI) [47]:

$$\text{NDPTI}(x, y, t) = \frac{T(x, y, 0) - T(x, y, t)}{T(x, y, 0) + T(x, y, t)} \tag{22.16}$$

Automatic processing requires definition of thresholds, which can extract only “hot spots” or “cold spots” in the image (i.e., pixels with a value lower than the threshold will compose an image background, while pixels with a value equal or greater than the threshold will compose — “hot spots”). Because popular indexes are constructed to indicate higher probability of detected elements by a higher index value (low values — “cold spots”; high values — “hot spots”) it is possible to calculate a negative NDPTI image, too.

$$\text{NPTI}(x, y, t) = 1 - \text{NDPTI}(x, y, t) = \frac{2 * T(x, y, t)}{T(x, y, 0) + T(x, y, t)} \tag{22.17}$$

The signal to noise ratio (SNR) of this technique is rather small. It can be improved by averaging images, repeating the pulse excitation with time interval long enough for proper cooling.

As an example Figure 22.5a is a photograph of the burns caused by fire. Figure 22.5b,c show fields of IIa/b degree burn evidenced at the first and the second day after the accident. The effect of treatment is also very well visible comparing the results of measurements done day by day. In the related example the burn area was small enough to avoid grafting.

**FIGURE 22.5** Patient with burn wound, first day after the accident — photograph of the burn (a), NDPTI image of the same field (b), and the NDPTI image at the second day (c)

### 22.6.2 Active Dynamic Thermal IR-Imaging

The ADT is based on comparison of measurements with a simple multilayer thermal model described by Equation 22.4 and Equation 22.5 giving a simplified description of parametric images of thermal time constants, which values are correlated with internal structure of tested objects [11,48]. Recorded in time thermal transients at a given pixel are described by exponential models. Here, the two exponential models are describing the process of natural cooling after switching the heating pulse off.

$$T(t) = T_{\min} + \Delta T_1 e^{-t/\tau_{1c}} + \Delta T_2 e^{-t/\tau_{2c}} \quad (22.18)$$

Model based identification of a tested structure (object) is performed as it is shown in Figure 22.2. The recorded thermal response is fitted to a model. In many cases the two exponential description is fully sufficient for practical applications. As an example, typical transient in time for a single pixel (e.g., from Figure 22.5) is shown in Figure 22.6, with fitting procedure applied to one and two exponential models.

The two exponential models, as Equation 22.18, are fully sufficient for the data of accuracy available in the performed experiment. Some more pictures and examples of the ADT procedure are shown in following paragraphs, especially in skin burn evaluation [49,50]. It should be underlined that time constants for the heating phase  $\tau_h$  and for the cooling phase  $\tau_c$  usually are different due to different heat flow paths.

### 22.6.3 Pulse Phase Thermography

The procedure of PPT [2,51] is based on Fourier transform. The sequence of infrared images is obtained as in conventional PT experiments, Figure 22.7. Next, for each pixel  $(x, y)$  in every of  $N$  images the temporal evolution  $g_i(t)$  is extracted and then the discrete Fourier transform is performed using the formula:

$$F_i(f) = \frac{1}{N} \sum_{n=0}^{N-1} g_i(t) \exp\left(\frac{-j2\pi f t}{N}\right) = \text{Re}_i(f) + j\text{Im}_i(f) \quad (22.19)$$

$$\varphi_i(f) = \text{atan}\left(\frac{\text{Im}_i(f)}{\text{Re}_i(f)}\right); \quad A_i(f) = \sqrt{\text{Re}_i(f)^2 + \text{Im}_i(f)^2}$$

More valuable diagnostic information is given in the phase shift; therefore this parameter is of major interest.

Interesting characteristics of PPT are evident since it combines the speed of PT with the features of lock-in approach (the phase and the magnitude image). The condition to get reliable results is application of fast and very high quality IR cameras.

As this method was not applied in medicine, yet, we do not show any examples, but extensive discussion of the validity of the procedure may be found in Reference 51.

### 22.6.4 Thermal Tomography

Thermal tomography should allow tomographic visualization of 3D structures, solving the real inverse problem — find distribution of thermal conductivity inside a tested object. This attempt is fully successful in the case of skin burn evaluation [16–18], giving a powerful tool in hands of medical doctors allowing reliable quantitative evaluation of the burn depth [52–54]. Other applications are under intensive research [55–57].

In TT the first step is determination of thermal properties of a tested object, necessary for development of its thermal equivalent model, to be applied for further data treatment. A typical procedure allowing the model parameters determination is shown in Figure 22.8. The forward problem is solved and assumed model parameters are modified to satisfy a chosen criterion for model and measurement data comparison.

FIGURE 22.6 Fitting of the models to the measurement data — 5-parameter model (a) and 3-parameter model (b).

The second step is organization of an active dynamic thermography experiment and registration of thermal transients forced by external excitation.

The next step requires advanced calculations to solve the inverse problem. The information of the correlation of the calculated figure of merit with a specific diagnostic feature is necessary to take a proper diagnostic decision based on the performed measurements. The decision function is directed to determine the internal thermal structure of the tested object basing on thermal transients at its surface. In this case, a real inverse problem has to be solved. We perform this procedure using Matlab scripts [17,18]. As the result a multilayer structure of different thermal properties may be reconstructed. To solve this problem additional assumptions, as number of layers, values of thermal properties or dimensions, are necessary because in general the problem is mathematically ill posed and nonlinear.

The method allows, under some conditions, not only to calculate the thermal effusivity, but also to reconstruct thermal diffusivity distribution in a layered structure. It is done using the nonlinear least

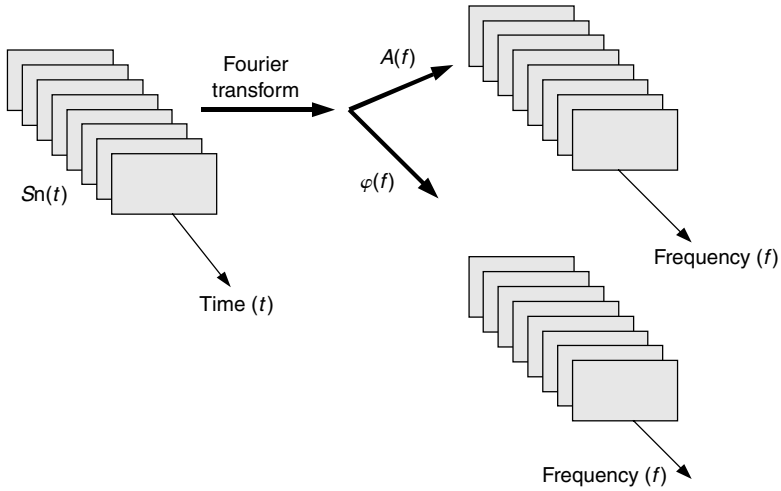

FIGURE 22.7 Procedure of calculation of synthetic pictures in PPT.

FIGURE 22.8 Determination of model parameters, based on comparison of measurement and simulation data, valid for all kind of tomography.

square optimization algorithm in inversion of direct problem:

$$\left. \begin{matrix} T_0(x) \\ T_{exc} \\ \Phi(0, t) \\ k(0) \end{matrix} \right\} \Rightarrow \alpha(x) \tag{22.20}$$

where  $T_0(x)$  is the initial temperature distribution in the object,  $T_{exc}$  the temperature of the heater,  $\Phi(0, t)$  the heat flux at the surface, and  $k(0)$  is the thermal conductivity of the outermost layer. In medical diagnostics of burn depth determination the problem is defined in a discrete form allowing determination of the parameter  $D$ , describing the depth of specific thermal properties, for example, depth of the burned tissue (the unknown parameter is local thickness of the tested object  $d = D \cdot \Delta x$ ):

$$\left. \begin{matrix} T_m^1, \quad m = 1 \dots M \\ \Phi_{exc} \\ T_1^p, \quad p = 1 \dots P \\ [k_m, \rho c_m]_{m \leq D} = [k_{rub}, \rho c_{rub}] \\ [k_m, \rho c_m]_{D < m < M} = [k_{air}, \rho c_{air}] \end{matrix} \right\} \Rightarrow D \tag{22.21}$$

FIGURE 22.9 Spatial discretization of the properties of a multilayer object under test.

where the upper indexes describe the time domain and lower — the space domain. The inverse problem allows solution for which the direct simulation of temperature distribution is closest to the experiment results. This is by solving the problem, which is set by the goal function  $F(D)$ :

$$F(D) = \sum_{p=1}^P (T_{dir}^p(D) - T_{meas}^p)^2 \xrightarrow{D} \min \tag{22.22}$$

where  $T_{dir}^p$  is the surface temperature for simulation performed for assumed value of the parameter  $D$  and  $T_{meas}^p$  the values measured. In the following examples the Matlab *lsqnonlin* function was adopted to solve this problem basing on modified interior-reflective Newton method [18]. Description of multilayer structures is also possible and may be defined in the form illustrated in Figure 22.9 [18,54]. One directional flow of heat energy is assumed.

What should be underlined is that the TT procedure requires advanced calculations and very reliable data, both from measurements as well as for modeling. Comparing to ADT this is much more demanding method, therefore it seems that typical for ADT description using thermal time constants at present stage of development seems to be easier accepted by medical staff.

## 22.7 Experiments and Applications

There are three groups of study performed:

1. On phantoms, for evaluation of technical aspects of instrumentation to be applied for *in vivo* experiments
2. On animals, *in vivo* experiments, for reference data
3. Clinical, for evaluation of the practical meaning of applied procedures

As the ADT as well as TT methods are new in medical diagnostics here we show some results of animal *in vivo* experiments and a few clinical cases. Described applications concern burns diagnostics and evaluation of cardiosurgery interventions. Results of phantom experiments and some other clinical applications were described in other cited publications, for example, References 22, 26, and 43.

### 22.7.1 Organization of Experiments

The clinical trials are done in *the Department of Plastic Surgery and Burns Treatment*, and in *the Department of Cardiac Surgery and Cardiology* of the Medical University of Gdansk. The leading medical personnel had all necessary legal rights for carrying the experiments, approved by the local ethical commission. All clinical experiments were done during normal diagnostic or treatment procedures, as the applied PT, ADT, and TT are noninvasive, aseptic, and safe. The excess of evoked surface temperature rise is around 2 to 4°C and the observation by the IR-camera is taken from a distance of 1 m. For skin temperature

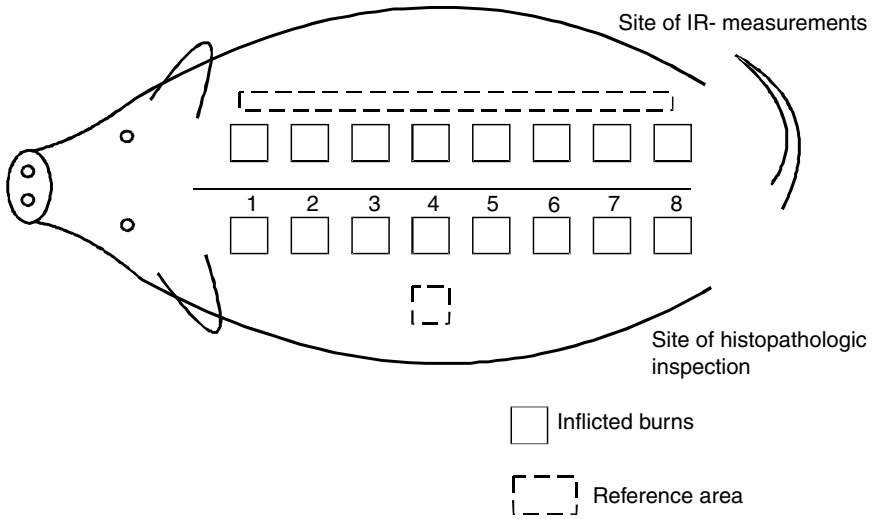

FIGURE 22.10 Location of experimental burns.

measurements illuminated area usually is kept wet using a thin layer of ointment to satisfy condition of constant evaporation from a tested surface and a constant value of emissivity coefficient. In cardiac surgery experiments with open chest, the surface of the heart is observed where the conditions of emissivity are regarded as constant. The IR-camera is located in a way not disturbing any activity of a surgeon.

The *in vivo* experiments on domestic pigs were performed in the Department of Animal Physiology, Gdansk University. The research program received a positive opinion of the institutional board of medical ethics. Housing and care of animals were in accordance with the national regulations concerning experiments on living animals. The choice of animals was intentional. No other animals have skin, blood, or heart properties so close to the human organs than pigs do [45]. Therefore, the experimental data carrying important medical information are of direct relationship to human organ properties.

Our burn experiments were based on the research of Singer et al. [58] and his methodology on standardized burn model. Following his experiment more than 120 paired sets of burns were inflicted on the back skin of 14 young domestic anesthetized pigs using aluminum and copper bars preheated in water in the range from 60 to 100°C. Typical distribution of burns is shown in Figure 22.10. Each pair was representing different conditions of injury giving a set of controlled burn depths. Additionally, each of measuring points was controlled by full-thickness skin biopsies and followed by histopathologic analysis of burn depth. The results of skin burn degree are in good accordance to the data given by Singer. The pigs were maintained under a surgical plane of anesthesia in conditioned environment of 24°C. The back skin was clipped before creation of burns. The total body surface area of the burns in each pig was approximately 4%. The animals were observed and treated against pain or discomfort.

After the “burns” experiment completed the same pigs were anesthetized, intubated and used for experimental myocardial infarction by closing the left descending artery. This experiment was lasting 5 h to evidence the nonreciprocal changes of the heart muscle. Full histopathology investigation was performed for objective evaluation of necrosis process.

Basic measurement set-up used in our experiments is composed of instruments shown in Figure 22.4. It is consisting the Agema 900 thermographic camera system; IR incandescent lamps of different power or a set of halogen lamps (up to 1000 W) with mechanical shutter or an air-cooling fan as thermal excitation sources; a control unit for driving the system. Additionally a specially designed meter of tissue thermal properties is used to determine the contact reference data necessary for reliable model of the skin or other tissue.

**FIGURE 22.11** (a) Anatomy of the skin [59], (b) three-layer structural model, and (c) equivalent thermo-electric model.

The initial assumptions applied for reconstruction of a tested structure using ADT and TT procedures:

- Tested tissue is a 2- or 3D medium with two- or three-layer composite structure (e.g., for skin — epidermis, dermis, subcutaneous tissue); (but for simplicity and having limited performance instrumentation even one layer model may be useful for diagnostic use in tissue evaluation).
- Tissue properties are independent on its initial temperature.

For skin and under-skin tissues an equivalent three-layer thermal model was developed [11]. For the assumed model its effective parameters have been reconstructed basing on the results of transient thermal processes. For known thermal diffusivity and conductivity of specific tissues the local thickness of a two- or three-layer structure may be calculated. In the structural model, each layer should correspond to the anatomy structure of the skin (see Figure 22.11). But in the case of a well developed burn a two-layer model is sufficient as the skin is totally changed and the new structure is determined by the died burned layer and modified by injury internal structure of thermal properties drastically different comparing the pre-injury state.

## 22.7.2 Results and Discussion

The related results are divided into groups covering clinical measurements of skin burns and heart surgery and equivalent measurements on pigs. The animal experiments are especially valuable to show importance of the discussed methods. Such experiments assure conditions which may be regarded as reference because fully controlled interventions and objective histopathologic investigations have been performed in this case.

## 22.7.3 Skin Burns

### 22.7.3.1 *In Vivo* Experiments on Pigs

The measurements were performed approximately 0.5 h after the burn creation and were repeated after 2 and 5 h and every 24 h during 5 consecutive days after the injury. As the ADT and TT experiments are new in medicine there are several notices concerning methodology of experiments. Especially some biological factors are of high importance. The pigs are growing in extremely fast; therefore the conditions of measurements are constantly changed. Also the hairs grow anew changing the measurement conditions and cannot be clipped again as the area is affected by injury. This was especially important for direct contact measurements but was not influencing IR measurements. The position of animals in consecutive days was not always the same causing some problems with data interpretation. The results of biopsy and histopathologic observations are used as the reference data of the skin burn thickness. We indicated the same set of parameters as given by Singer, what is shown in Figure 22.12 for exemplary burns of one of the pigs. The affected thickness of skin is dependent on the temperature and time of the aluminum and copper bars application. The plots are showing relative thickness of a burn with respect to the thickness of the skin. Such normalization may be important as the skin is of different thickness along the body. All affected points have full histopathologic description. Here only one example

**FIGURE 22.12** Relative thickness of the burned skin for several aluminum bar temperatures for time of application equal 30 sec — different indicators describing burns are listed (biopsy results).

**FIGURE 22.13** (See color insert following page 29-16.) Classical thermogram (a) and PT normalized differential thermography index pictures of burns (b) and (c).

is shown for points of the aluminum bar applications of different temperature but constant 30 sec time of application.

Some thermographic data of one of pigs taken 5 h after the burn injury are shown in Figure 22.13a [11]. A thermogram while heating is switched off with indicated six measurement areas is shown. Two bottom fields are uninjured reference points, four other are burns made using the aluminum bar — from the left: 100°C/30 sec; 100°C/10 sec and 90°C/30 sec; 80°C/30 sec. The set of halogen lamps was applied for PT and ADT experiment. The result of NDPTI pictures show temperature distribution 100 and 200 msec after the excitation Figure 22.13b,c. The burns are clearly visible and the relative temperature rise is very strongly correlated to the condition of the injury. For the indicated areas the mean value of temperature changes are calculated. This is shown for the first phase of cooling in Figure 22.14. The data might be fitted to thermal models giving ADT specific synthetic pictures of thermal time constants. The quality of the fitting procedure of measurement data to the equivalent model parameters is shown as an example in Figure 22.6a,b for one and two layer models.

There is a possibility to transform each of pixels into the equivalent model descriptor. In Figure 22.15a to Figure 22.15 f thermograms taken in consecutive days are transformed according to the formula  $A \exp(-R_0 t)$ . Distribution of the parameter — the thermal time constant — is shown.

Diagnostic importance of thermal transients is especially clearly visible in Figure 22.16 [18], where different injuries are responding differently to thermal excitation. The line mode of the IR-camera is here applied for fast data registration (>3000 scans/sec), allowing reduction of noise.

FIGURE 22.14 The normalized averaged temperature changes at the first phase after the excitation is switched off for indicated in Figure 22.13a points.

Basing on the same material TT procedure and reconstruction of thermal conductivity is also possible [18,54]. Assuming that we know the initial state of the object, the value of excitation flux, thermal response on the surface and spatial distribution of volumetric specific heat within the object it is possible to find the distribution of thermal conductivity:

$$\left. \begin{array}{l} T_m^1, m = 1, \dots, M \\ \Phi_{exc} \\ T_1^p, p = 1, \dots, P \\ \rho c_m, m = 1, \dots, M \end{array} \right\} \implies k_m, \quad m = 1, \dots, M \tag{22.23}$$

The inverse problem defined by Equation 22.23 is highly justified due to practical reasons: the volumetric specific heat of biological tissues is much less dependent on water and fat content and other physiological factors than thermal conductivity is (especially effective thermal conductivity, which includes blood perfusion) [45]. Hence, the distribution of  $\rho c(x)$  may be regarded with good approximation as known, and irregularities in thermal conductivity distribution should be searched for.

Figure 22.17 presents the results of minimization based on measurements taken during experiments with controlled degree burn fields as it was shown in Figure 22.16. The distribution of specific heat has been assumed identical with the healthy tissue, because of its low dependency on burn [18]. On the reconstructed thermal tomogram, a distinct layered structure of the skin can be seen, as well as the changes in its thermal structure caused by burns. The outermost two slices (0–0.2 mm) represent the epidermis and have thermal conductivity close to  $0.3 \text{ W m}^{-1} \text{ K}^{-1}$ , which is almost not affected by burns. Fundamental changes in thermal properties induced by burns may be noticed in the next four slices (0.2–0.5 mm). From the anatomical point of view, this region represents the superficial plexus and adjacent layer of the dermis. As one can expect, for superficial burns we observe increase of  $k$  in this region, and decrease of  $k$  for severe burns. Based on this observation, quantitative classification criteria can be proposed [18].

For examination of skin burns is seems optimal to implement the expression 22.23. It allows obtaining thermal tomography images, which reflect pathologic changes in thermal conductivity distribution up to 2 to 3 mm.

**FIGURE 22.15** Thermal time constant representation for the same case as showed in Figure 22.13 and Figure 22.14 in consecutive days, starting from the moment of injury (upper left) and ending on the 5th day (bottom right). The placement of injures seems to be shifted due to different positions of the animal from day to day. Specific burn areas are easy recognizable. Additional studies are necessary for making full diagnostic medical recognition of injury, as there are two factors influencing each other — healing process and fast growth of the animal.

### 22.7.4 Clinics

We have examined around 100 patients with different skin injuries. Burn injuries were formed in different accidents as a result of flame action directly on skin, hands and faces, and on burning clothes, thorax. The investigations were performed during the first 5 days following an accident. To illustrate the clinical importance of the discussed methods an example of burns caused by an accident is shown in Figure 22.5. The well-determined area of the second-degree burn is evident. The next step — after rising more clinical data — will be quantitative classification based on data of the burn thickness. Long lasting effects of treatment and scars formation are still studied and not related here, yet. Already we claim that the value of the thermal time constant taken at the second day after the accident allows quantitative, objective discrimination between IIa and IIb burn [Renkielska, to be published].

### 22.7.5 Cardiac Surgery

#### 22.7.5.1 *In Vivo* Experiments on Pigs

Understanding of thermal processes existing during the open chest heart operations is essential for proper surgical interventions, performed for saving the life. Experiments on pigs may be giving answers to several

FIGURE 22.16 (See color insert.) Thermal transients of burn fields of degree: I, IIa, IIb, IIb.

FIGURE 22.17 Results of the reconstruction of thermal conductivity distribution in burn fields.

important questions impossible to be responded in clinical situations. This especially may concern sudden heart temperature changes and proper interpretation of the causes.

Clamping the left descending artery and evoking a heart infarct performs the study. Temperature changes have been correlated with the histopathologic observations. The macroscopic thickness of the necrosis was evaluated. This was confirmed by the microscopic data. In Figure 22.18a anatomy of the

**FIGURE 22.18** (See color insert.) Pig's heart after heart infarct evoked by the indicated clamp (a), the cross section of the heart with visible area of the stroke (the necrosis of the left ventricle wall — under the finger — is evidenced by darker shadow) (b) and the micro-histopathologic picture showing the cell necrosis (c).

**FIGURE 22.19** (See color insert.) Thermograms of the heart: before (a) and after the evoked infarct (b). The change of the PT/ADT pictures in time (indicated in the subscript of the thermogram) 0.5 h after the LAD clamping (the tissue is still alive) (c) and 3 h later (the necrosis is evidenced by the change of thermal properties of the tissue) (d).

heart with the clamp is shown. The cross-section line is visible. In the Figure 22.18b the macroscopic cross-section is shown and the evidence of tissue necrosis is by the microscopic histopathology is shown in Figure 22.18c. The widths of the left and right ventricle as well as septum were also measured. The mass of the necrosis tissue was calculated. The evident correlation between the thickness of the left and right ventricle walls and the thermographic data are found. Thermographic views of this heart are shown in Figure 22.19a,b respectively before and after application of the clamp. The left ventricle wall is cooling faster than the right one as the left ventricle wall thickness is bigger and the heating effect caused by the flowing blood (of the same temperature in both ventricles) is here weaker. The cooling process of the heart caused by stopping the blood flow in LAD is shown in Figure 22.20 — the mean temperature changes of the indicated in Figure 22.18a regions AR01 and AR02 are plotted.

FIGURE 22.20 Temperature changes of the left and right ventricle after the LAD clamping related to Figure 22.19a,b.

The PT/ADT picture 0.5 h after the clamp was applied (Figure 22.19c) is still showing that thermal properties of the walls are unchanged even the temperature of the left ventricle wall is evidently decreased (Figure 22.19b). Progressing in time the necrosis process is changing thermal tissue properties what is clearly visible after 3 h in Figure 22.19d.

### 22.7.6 Clinics

Operation under extracorporeal circulation is normally a typical clinical situation. Two cases before and after CABG — coronary artery by-pass grafting — are shown for ADT in Figure 22.21a,b respectively. Areas of necrosis and of ischemia as well as volume of the healthy heart muscle were evaluated in respect to coronarangiographic and radioisotope data showing high correlation. The observations performed before and after CABG show evident recovery of heart functioning. It is evidenced by smaller temperature rise after optical excitation of the heart in the same conditions. ADT shows the level and efficiency of revascularisation. The region of heart muscle dysfunction due to heart stroke was possible to be differentiated using both — normal thermography as well as ADT method — what leads to the conclusion that both modalities should be taken into account for diagnostics. The application of thermography for instant evaluation of the quality of the CABG intervention is prompt — the patency of the LIMA — LAD graft is unbeatable by any other method [60], but thermal tissue properties reflecting real state of the tissue is given only by ADT.

Application of all discussed modalities PT, ADT, PPT, and TT during the cardiosurgical interventions gives important indications how to improve surgical procedures.

## 22.8 Conclusions

The study shows that ADT as well as TT have been successfully used in medical applications giving not only qualitative improvement of diagnostics but in several applications allowing also quantitative evaluation of affected structures.

The importance of active dynamic thermal imaging and thermal tomography applied to burn evaluation and in the inspection of the open chest cardiology interventions was verified. Most probably there are also other attractive fields of medical applications of ADT and TT as, for example, cancer diagnostics [60]. ADT can be applied in medical procedures for monitoring the state of the skin and subdermal tissue structure during burns treatment giving objective, measurable ratings of the treatment procedure. The moment

**FIGURE 22.21** (See color insert.) ADT picture of clinical intervention — before the CABG (a) and after the operation (b). Important is more uniform temperature distribution after the operation proving that intervention was fully successful.

of thermal investigation after an accident is of the highest significance. The most valuable results are obtained during the first and the second days following an accident. The clinical valuable features of the method in skin burns evaluation are the early objective determination of the burn depth — up to two days after an accident and possibility of quantitative evaluation of burn surface and depth as well as objective classification of burn degree. Also, the monitoring role of the method in interoperation of cardiac protection seems to be unbeatable. Changes of tissue vascularisation are important for prediction of treatment progress. In all applications, the method is noncontact, noninvasive, clean and nonstressed, allows wide area of investigation and clear and objective documentation of diagnoses and treatment process.

The use of different excitation sources should be limited to those of the best measurement properties. Basing on the described experiments most handy are optical sources of irradiation but probably cooling may give even better results in terms of higher signal to noise ratio. The operation of such sources is safe, harmful, and easy. The distribution of light may be relatively uniform; the control of irradiated power is also easy.

The work in the field of ADT and TT is still under fast development. Important is extensive IR instrumentation progress giving radical imaging improvement. The problem to be solved is development of a method of noncontact automatic determination of basic properties of thermal parameters of affected tissue what is one of main tasks for the future. Special software is under development for objective and automatic generation of affected tissue depth maps. Important will be to find not only qualitative information but also application of quantitative measures; to describe ratings of the burn wounds or calculate the thickness of affected heart tissues. Still more experiments giving statistically significant knowledge are necessary.

One of important goals is combination of different modalities and application of automatic classification procedures for improved diagnostics. This requires some progress in standardization of IR imaging, which still is not offered in the DICOM standard. For sure, distant consultation of images and automatic data retrieval will be pushing proper work in this field.

## Acknowledgments

The author thanks his co-workers and Ph.D. students, who participated in development of ADT & TT in medicine and who produced the presented data. Most of the reported *in vivo* experiments have been performed with the help of Dr M. Kaczmarek, Dr M. Hryciuk, A. Galikowski and others from the Department of Biomedical Engineering, Gdansk University of Technology. Participation of medical staff: Dr A. Renkielska and Dr J. Grudziński (from the Department of Plastic Surgery and Burns Treatment), Prof. J. Siebert (from the Department of Cardiac Surgery and Cardiology, Medical University of Gdansk) and others are highly appreciated. *In vivo* animal experiments have been performed at the Department of Animal Physiology, Gdansk University with the main assistance of Dr W. Stojek. Others are listed in the attached bibliography as coauthors of common publications. The work was supported by several grants from KBN (Polish Ministry of Science and Information).

## 23.1 Introduction

---

Due to the progress of society and increasing health concerns, the health issue is becoming more and more important. However, thousands of years of practice in the medical field presented us with the fact that humans intend to play a passive role in the process of fighting diseases. We may keep track of some diseases by resorting to modern medicine. However, we are not content and still lag far behind in understanding the root of the disease, performing initial and early detection, as well as finding the linkage between the disease and the organization of the human body. Working on solutions to these issues have pushed forward the birth of an innovative health monitoring and treatment evaluation technology, thermal texture maps (TTM).

The TTM evaluation technology mainly concerns the study of functions of living cells. Unlike other imaging techniques such as computer tomography (CT) and magnetic resonance imaging (MRT) that primarily provide information on the anatomical structures, TTM is more sensitive and provides functional information not easily measured by other methods. In addition, this technology is based on the detection of heat radiation generated by metabolic activities of living cells, thus is noninvasive and environmental friendly.

In this chapter, we introduce the concept and theory of the TTM technology. We also present its applications in early detection of breast cancer, estimate of tumor size, comparative study of breast cancer detection with mammography and ultrasound, diagnosis of severe acute respiratory syndrome (SARS) patients, and the trilogy-imaging characteristics of TTM.

## 23.2 Medical Evaluation of TTM — Present and Future

---

### 23.2.1 The Development Status of TTM

Functional medical imaging technology has been the mainstream in the technological world during the past few decades. The end of 1990s witnessed a breakthrough brought by a group of scientists and engineers in China. Based on their extensive experience working with CT, MRI, and Ultrasound, they have initiated the development of a new generation functional imaging technology, TTMs, with which the metabolic activities within a human body can be detected and analyzed from the radiation heat generated by the human body cells. With a decade of efforts, they finally discovered the relationship between the surface temperature distribution and the internal heat source of the human body. Their research findings are supported by several years of clinical studies. In 1997, a patent application for the TTM technology was made to the Food and Drug Administration (FDA) of the United States as well as 93 other countries' patent offices for patent protection. The patent was granted by the United States on February 2, 2000.

A company named Bioyear Group was formed in 1995 in Beijing, China, dedicated to the research and development work on TTM. In 1997, the U.S.-based Bioyear company (now TTM International) was incorporated and the first thermal infrared (TIR) imaging scanner with slicing capability hit the market. Since then, a series of thermo-scanner imaging (TSI) products has been manufactured and shipped to Chinese hospitals. In 1998, a brand new TSI system that adopted uncooled infrared detector was shipped to China, the United States, and Canadian hospitals for clinical studies.

The first public announcement of the TTM technology in the United States took place at the special event "From Tanks to Tumors: A Workshop on the Application of IR Imaging and Automatic Target Recognition (ATR) Image Processing for Early Detection of Breast Cancer," held in Arlington, Virginia, United States, December 4–6, 2001 (see Chapter 1 for details). On July 4–6, 2002, at the IEEE International Symposium on Biomedical Imaging, TTM technology was first presented at a major international conference and has generated considerable interest in the audience. Since then, TTM technology has been discussed among researchers worldwide at the IEEE Engineering on Medicine and Biology Society Annual Conferences, in the format of training workshop, mini-symposium, as well as technical talks. In China, to speed up the pragmatic deployment of the TTM technology, a specially tailored conference, sponsored by the Chinese Ministry of Health, was held at the Xiangshan Science Conference Center in Beijing, 2003. To assess

the usefulness of the TTM technology, the technical committee of the conference were members from the Academy of Science, Engineering, and Medicine, including professors and physicians from selective universities and medical centers.

To date, more than 100 medical units in China are equipped with TTM facilities. Since 2001, NIH has been using TTM technology for studies in skin cancers. In addition, TTM was used successfully during the SARS outbreak at the beginning of 2003. Significant results have been achieved then. At present, mass production of TTM scanners is under consideration in order to bring the technology to the benefit of human health as soon as possible.

### **23.2.2 Existing Problems and Expectations**

The next improvement of TTM technology needs to be based on basic research in engineering and clinical studies. The important area of basic engineering research work should concentrate on the relationship between surface heat distribution and the estimation of single heat source's depth and size information under complicated situations. More importantly, this estimation needs to also consider multi heat sources condition. Some very encouraging preliminary results have been achieved in the definition of relationship between surface heat distribution and heat source size estimation.

Standard database generation is another factor to be considered for the improvement and evaluation of TTM technology. The healthy growth and benefits of TTM technology will certainly build on the standardization of training and operation. The engineering world should produce practical and simple mobile machines to satisfy multi-purpose requirements, also they should produce cost-effective machines for medium size hospitals.

Research and development in detector will certainly influence the advance of TTM technology in the future. As uncooled detectors and scanners are being manufactured with low cost, high sensitivity, high accuracy, and high stability, direct influence is expected on the popularization and improvement of the TTM technology.

## **23.3 TTM Theory and Application in Early Breast Cancer Diagnosis**

---

### **23.3.1 Introduction**

All objects at a temperature above absolute zero emit electromagnetic radiation spontaneously, called the natural thermal radiation [1]. The heat emanating on to the surface from the cancerous tissue and the surrounding blood flow can be quantified using the Pennes [2] bio-heat equation [3]. This equation includes the heat transfer due to conduction through the tissue, the volumetric metabolic heat generation of the tissue, and the volumetric blood perfusion rate whose strength is considered to be the arterio-venous temperature difference. In theory, given the heat emanating from the surface of the body measured by IR imaging, by solving the inverse heat transfer problem, we can obtain the heat pattern of various internal elements of the body. Different methods of solving the bio-heat transfer equation have been presented in literature [4,5].

Although it is possible to calculate the thermal radiation from a thermal body by thermodynamics, the complexity of the boundary conditions associated with the biological body makes this approach impractical.

### **23.3.2 The Thermal–Electric Analog**

This section presents a new method for analyzing a thermal system based on an analogy to electrical circuit theory; referred to as thermal–electric analog [6]. We demonstrate how the analog can be used to estimate the depth of the heat source, and furthermore, help understand the metabolic activities undergoing within the human body. The method has been used in early breast cancer detection and has achieved high

FIGURE 23.1 The thermal–electric analog (© 2005 IEEE).

sensitivity. Several breast cancer study cases are given to show the effectiveness of the method. Ongoing clinical study results are provided as well.

As the living cells within a biological body are constantly undergoing metabolic activities, the biochemical and the physical metabolic processes generate heat. Thus the amount of radiation on the surface of the human body can reflect its metabolic rate. The theory underlying conventional thermographic techniques as applied to cancer is that the change of the pulse distribution around a cancerous area and the rate of metabolism are greater than the general tissue, resulting in a higher temperature at the skin surface [6].

Even though the temperature of the skin surface can be measured, if the relationship between the surface temperature and the emissions from inside of the body cannot be established, the application of TIR imaging technique is still limited. Pennes’ bio-heat equation models the process of heat transfer but has its limits in practice. Thus, a new method that does not require a direct solution to the inverse heat transfer problem, the thermal–electric analog, comes into light.

Figure 23.1 illustrates the analogy between thermodynamics systems and the electrical circuit, where the heat source  $S$  inside the human body can be simulated as a battery with voltage  $U_S$ , the heat loss inside the heat source can be simulated as the heat loss on a resistor  $R_S$ . The temperature of the heat source can then correspond to the voltage of the battery, and the heat current to the circuit current. Similarly, we can map the heat source in the air (outside the human body) as  $U_A$ , and the heat loss as  $R_A$ . The set of  $R_i$ s and  $C_i$ s corresponds to the unit heat resistance and heat capacity along each radiation line. The circuit in Figure 23.1 only shows the analogy for one radiation line. In the study of breast cancer, it is reasonable to assume that the medium between the heat source ( $S$ ) and the surface is homogeneous. Therefore, the radiation pattern sensed by the IR camera at the surface should have a distribution like Gaussian as shown in Figure 23.1. The surface temperature  $H(x)$  which corresponds to the output voltage can then be calculated by

$$H(x) = U_S - \frac{\sum_{i=1}^n R_i}{R_S + R_A + \sum_{i=1}^n R_i} \times (U_S - U_A)$$

and

$$n = \left\lfloor \frac{D}{R_0 \cos a} \right\rfloor$$

where  $\lfloor a \rfloor$  represents the largest integer less than  $a$ ,  $n$  is the number of resistors used in the circuit,  $D$  is the depth of the heat source, and  $R_0$  is the unit heat loss in a certain medium (or the heat resistance rate). Different parts of human body have different heat resistance rate, as shown in Table 23.1.

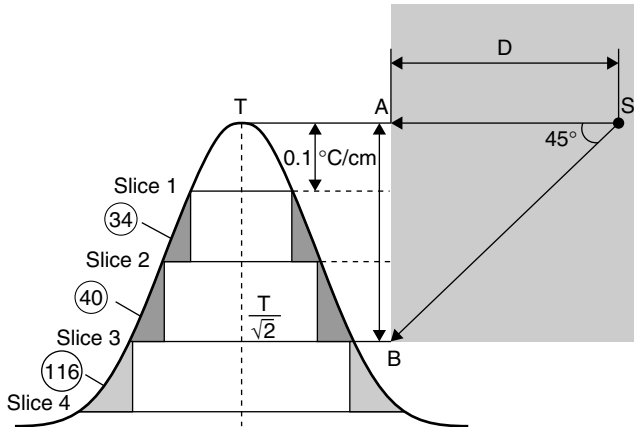

The thermal–electric analog provides a convenient way to estimate the depth of the heat source.

### 23.3.3 Estimation of the Depth of the Heat Source

The depth estimation is based on the assumption that we can use Gaussian to model the distribution of the surface temperature. A half power point is a useful property of Gaussian distribution. The property

**TABLE 23.1** Heat Resistance Rate of Different Body Parts

Body parts	Heat resistance rate ( $^{\circ}\text{C}/\text{cm}$ )
Fatty tissue	0.1–0.15
Muscle	0.2
Bone	0.3–0.6

**FIGURE 23.2** Illustration of half power point of Gaussian and the depth of the heat source (©2005 IEEE).

says that the half power point divides the area enclosed by the Gaussian into equally half. If we slice the Gaussian from top to bottom at a fixed interval as shown in Figure 23.2, the increment of the radius in the horizontal direction would not have dramatic change until the half power point is crossed. From Figure 23.2, we can see that the relative increment of the radius between the first slice and the second slice is 34 pixels, and 40 pixels between the second slice and the third slice, but 116 pixels between the third slice and the fourth slice. Therefore, the half power point is at the position of the third slice.

Suppose the temperature of the heat source is  $H_0$ . In the right triangle formed by SAB, the hypotenuse (SB) is equal to  $H_0$  and the sides ( $SA = AB$ ) should be equal to  $0.707H_0$ . The horizontal side (SA) is the depth of the heat source, and the vertical side (AB) is the temperature drop between the maximum value of the Gaussian and the half power point. In other words, if we can find the half power point, we can find the depth of the heat source.

Each slice of the Gaussian curve corresponds to a temperature deduction of 0.1 degree. For the application of breast cancer detection, based on the heat resistance rate of fat tissues, the 0.1 degree temperature drop corresponds to a distance of 1 cm. Therefore, by slicing (decreasing) the surface temperature at a certain degree per step, we can find the half power point with the accuracy at the level of centimeter.

### 23.3.4 Experimental Results and Analysis

Figure 23.3 shows a synthetic example of how slicing works. The image is taken from a piece of pork fat. An electric bulb is lit and inserted at the center of the pork fat as a heat source such that we can control the location of the heat source. The pseudo colormap is also shown in the figure. “White” represents the highest temperature and “black” represents the lowest temperature. First of all, an appropriate temperature needs to be found so that white pixels at the center of the pork fat will show up in the next slice. In this example, this appropriate temperature is  $20.50^{\circ}$ . Each following slicing process decreases the highest temperature in the color-map by 0.1 degree (e.g., the threshold is lowered by 0.1 degree), such that more white pixels can appear. If we come to a point where the increment of the white pixel is dramatic, the half power point

FIGURE 23.3 (See color insert following page 29-16.) Simulation of slicing operation on pork fat (©2005 IEEE).

FIGURE 23.4 (See color insert.) Slicing of patient with lobular carcinoma in the left breast (©2005 IEEE).

is the slice before it. In the example, the fourth slice generates much more white pixels than the previous three slices. The depth of the bulb is 3 cm, which is the same as the ground truth. Note that the increment of the white pixel is measured by the increment of the radius of the white cluster.

Besides measuring the depth of the heat source, slicing can also reveal the growth pattern of the white pixels. Dissimilar tissues have different growth patterns. By observing this pattern, different tissues can be distinguished as well. For example, the pixels of lymph nodes and tumors should grow in a circular pattern, while the growth pattern of blood vessel is along the direction of the blood vessel.

A diagnosis protocol has been designed for early detection of breast cancer. Six steps are involved in this protocol:

- Step 1: Growth pattern of lymph nodes in the armpits
- Step 2: Size of the abnormal area
- Step 3: Appearance of the abnormal area
- Step 4: Vascular pattern
- Step 5: Nipples and areola pattern
- Step 6: Dynamic diagnosis with outside agents (antibiotic, etc.)

Take the first step as an example, if the lymph nodes in the armpits reveal one heat source with a depth less than 2 cm, one abnormal sign (+) will be recorded; if two heat sources appear with a depth less than

FIGURE 23.5 (See color insert.) Slicing of patient with ductal carcinoma in the left breast (©2005 IEEE).

2 cm and a bilateral temperature difference greater than 0.2 degree, then two abnormal signs (++) will be recorded, etc.

Figure 23.4 shows a patient with lobular carcinoma in the left breast. From slicing, we observe the following abnormal signs:

1. 2 cm tumor surrounded by four blood vessels (+ + +)
2. White pixels surround the nipple in three slices (+ + +)
3. Nipple bilateral temperature difference is 0.8 degree (+)

Figure 23.5 shows a patient diagnosed to have ductal carcinoma in her left breast. From slicing, we observe the following abnormal signs:

1. Lymph node bilateral temperature difference is 0.8 (++++)
2. The tumor is 2 cm from the surface (++)
3. The tumor is surrounded by five blood vessels (+++)
4. It takes less than three slices to have the white pixels surround the nipple (++)

## 23.4 Relationship between Surface Temperature Distribution and Internal Heat Source Size of the *In Vitro* Tissue

### 23.4.1 Introduction

In contrast to traditional anatomical imaging technologies, such as X-CT and ultrasound, thermography is a functional imaging modality. Thermography obtains skin temperature distribution through detecting thermal radiation emanating from the human body surface. Thermograph is the image of surface temperature distribution. The skin temperature can reflect the metabolic rate of the human body. The patterns of thermograph are affected by the activities of the tissues, organs, and vessels inside the body [6].

As a noncontact and noninvasive imaging modality, thermography is widely used in clinical practice. The FDA, Bureau of Medical Devices has approved the thermography procedures, including the screening for breast cancer, extra-cranial vessel disease (head and neck vessels), neuro-musculo-skeletal disorders, and vascular disease of the lower extremities [7].

As pointed out in [8], a shift should occur in the study of thermography from phenomenological to pathophysiological. Currently, the application of thermography is limited if only the skin temperature is obtained. It would be desirable to provide a method for revealing the relationship between the skin temperature and internal heat sources. In order to clinically effectively detect and diagnose cancers (especially in their early stages) and other diseases, the depth and size information of internal heat sources hidden in the abnormal patterns of thermographs need to be discovered.

## 23.4.2 Method

### 23.4.2.1 Heat Transfer Formulation

In the field of bio-heat transfer [9], the basic formulation is the bio-heat equation, originally proposed by Pennes [2],

$$\rho c \frac{\partial T}{\partial t} = \nabla \cdot (k \nabla T) + Q_b + Q_m \quad (23.1)$$

where  $T$  is the local temperature,  $\nabla$  is the Laplace operator,  $\rho$ ,  $c$ , and  $k$  are the tissue density, specific heat, and the heat conductivity, respectively,  $Q_b$  is the Pennes perfusion term, and  $Q_m$  is the metabolic heat production.

Consider a simpler condition, in which the *in vitro* tissue in a stable state is heated by an internal heat source, then the bio-heat Equation 23.1 can be simplified to

$$\nabla \cdot (k \nabla T) = 0 \quad (23.2)$$

On the boundary, heat can be exchanged through radiation and convection with the environment. The convection on the boundary was considered as natural convection. And the radiation heat exchange can be induced from Stephan–Boltzman Law,

$$q_r = \sigma \varepsilon T_s^4 - \sigma \varepsilon T_0^4 \quad (23.3)$$

where  $q_r$  is the radiation heat exchange density,  $\sigma$  is the Stephan–Boltzman constant,  $\varepsilon$  is the surface emissivity,  $T_s$  is the surface temperature, and  $T_0$  is the environment temperature. In order to simplify the calculation, Equation 23.3 can be expressed as

$$q_r = h_r (T_s - T_0) \quad (23.4)$$

where  $h_r$  is the radiation heat exchange coefficient. Natural convection heat exchange is determined as

$$q_c = h_c (T_s - T_0) \quad (23.5)$$

where  $q_c$  is the convection heat exchange density,  $h_c$  is the convection heat exchange coefficient, and  $h_c$  can be calculated by an empirical formulation,

$$h_c = 1.57 (T_s - T_0)^{1/4} \quad (23.6)$$

The total heat exchange density  $q_e$  with environment on the boundary is the sum of the two heat exchange densities: the radiation heat exchange  $q_r$  and the convection heat exchange  $q_c$ .

$$q_e = q_r + q_c \quad (23.7)$$

Equation 23.2 can be solved only if the boundary conditions are complete and the solution is unique. However, the boundary conditions are very hard to be complete. Under the conditions described in Figure 23.6, that is, (1) the heat source is a sphere, (2) the *in vitro* tissue is isotropy, and (3) the *in vitro* tissue is a slab whose length and width is much larger than the sphere's radius, then some approximation can be made.

The first approximation is to assume that the solution to Equation 23.2 is a family of concentric spheres with the same center, that is, the center of the heat source. Using the spherical coordinate system,

**FIGURE 23.6** Conditions and approximation (©2005 IEEE).

Equation 23.2 can be expressed as

$$\frac{d}{d\rho} \left( \rho^2 \frac{dT}{d\rho} \right) = 0 \tag{23.8}$$

If the total heat emanating from the heat source is  $Q$ , the heat density of the spot at a distance  $\rho$  from the center of the heat source is

$$q = \frac{Q}{4\pi\rho^2} \tag{23.9}$$

The heat density also can be obtained through the Fourier's Law

$$\rho = -\frac{dT}{dq} \tag{23.10}$$

From Equation 23.8 and Equation 23.9, the temperature field function  $T(\rho)$  can be induced after integration

$$T(\rho) = T_1 - \frac{Q}{4\pi k} \left( \frac{1}{R} - \frac{1}{\rho} \right) \tag{23.11}$$

where  $T_1$  is the temperature of the heat source and  $R$  is the radius of the sphere.

The second approximation is to assume that at any spot of the boundary, heat density transferring from the internal heat source is fully exchanged with the environment, that is,

$$q_{in} = q_{out}$$

where

$$q_{in} = \frac{Q}{4\pi\rho^2} = k \frac{T_1 - T_D(r)}{\frac{\rho}{R}(\rho - R)}, \quad q_{out} = h_r(T_D(r) - T_0) + h_c(T_D(r) - T_0) = \alpha(T_D(r) - T_0)$$

and  $\alpha$  is the total heat exchange coefficient.

Finally the approximation solution of the boundary surface temperature distribution can be obtained

$$T_D(r) = T_0 + \frac{(T_1 - T_2)}{(\alpha/k) \cdot (\sqrt{D^2 + r^2}/R) \cdot (\sqrt{D^2 + r^2} - R) + 1} \tag{23.12}$$

where  $D$  is the distance from the surface to the center of the sphere.

In the following, the formulation of the approximation will be validated through experiments.

### 23.4.3 Experimental Design and Results

We design one experiment to validate the correctness of the approximation solution. The experimental setup is illustrated in Figure 23.7, in which three components are involved,

1. One piece of adipose hanged in the air, whose dimension is about  $15 \times 15 \times 2$  cm, served as the *in vitro* tissue
2. Four brass balls buried in the adipose, whose diameters are 5.07, 10.00, 15.44, and 19.77 mm, respectively, served as the internal heat source
3. One infrared camera (TSI-2 Bioyear Group, Inc.  $\pm 0.1^\circ$ ) that captures the surface temperature distribution onto a  $256 \times 256$  image

We first let the heater heat the brass ball through the heat conduction of brass bar. After about 2 h or so, the surface temperature distribution does not vary and reaches the stable state. Figure 23.8 shows the surface temperature distribution at the stable state.

Next, we generate the surface temperature distribution templates of the approximation solution corresponding to the four heat sources according to the experiment conditions as given in Table 23.2 and Figure 23.9 shows the generated templates.

Templates of the approximation solution are matched with the practical surface temperature distribution. We use the error energy Equation 23.13 and the normalized error energy Equation 23.14 to measure the closeness of the matching,

$$E = \sum \sum (mT - T)^2 \tag{23.13}$$

$$\tilde{E} = \frac{E}{\sum \sum T^2} \tag{23.14}$$

where  $mT$  is the surface temperature distribution template and  $T$  is the practical temperature distribution.

The matching results are given in Table 23.2 Both the error energy and the normalized error energy demonstrate quite low value, indicating the close match between the templates and the practical surface temperature distribution. It also validates the reasonability of the approximation solution.

### 23.4.4 Discussion

If a heat source is buried in the *in vitro* tissue, the tissue surface temperature distribution at the stable state will present a special pattern. The pattern of the temperature distribution reveals certain information about the internal heat source, such as the size. Through approximation, a simple relationship between surface temperature distribution and the size of the internal heat source is provided. The reasonability of the approximation is validated through the high degree of matching between the practical surface temperature distribution and the template generated by the approximation solution. It also validates the existence of the relationship between the surface temperature distribution and the internal heat source. Through this relationship, the internal heat source information can be obtained from the surface temperature distribution.

TABLE 23.3 Error Energy and Normalized Error Energy

Heat source diameter (mm)	Error energy	Normalized error energy ( $\times 10^{-5}$ )
5.07	491.91	6.35
10.00	533.87	6.73
15.44	657.72	8.23
19.77	570.10	7.06

## 23.5 A Comparative Study of Breast Disease Examination with Thermal Texture Mapping, Mammography, and Ultrasound

### 23.5.1 Introduction

In recent years, the occurrence of breast cancer has been steadily increasing. Doctors around the world are likely to be searching for a new type of methodology and technique, that can be used for screening breast cancer more easily and more specifically. TTM system, as one of the functional diagnostic procedures, may detect the abnormal metabolism of body tissues at an early stage. A group of 38 females with breast abnormalities, who were prepared for surgery, underwent double blind study using TTM, ultrasound, and mammography with molybdenum target tube (MMT). The diagnosis results from these three imaging modalities are compared with the pathological results after surgery. TTM was used to explore the position in differentiation between the benign and malignant breast abnormalities.

### 23.5.2 Material and Methods

Females ranging from 20 to 78 years old, 38 in number were hospitalized in the surgery sections of the 301 and 307 Hospital between December 20, 2003 and March 20, 2004. The main symptom was palpable masses in their breasts. After receiving TTM, ultrasonography, and MMT, all patients underwent surgery. Histology of the tumor sample demonstrated malignancy in 25 patients and benignity in the others.

The apparatus used for the study is a TSI-21 TTM system manufactured by Bioyear Group, Inc. Its main parameters include a thermal resolution of 0.1°C, a scanning period of 5 sec or less, and a scanning distance between 1 and 3 m.

The room temperature was controlled between 20 and 24°C, and the patients were asked to remove their clothes or just cover the lower part of the body after having 10 min rest. Their hands should not touch the body. After focusing, the images of the head, the breast and the abdomen were taken anteroposteriorly, adding breast oblique pictures from both sides. The abnormal thermo-sources in the images were digitized from tomography and the temperatures were measured for evaluation purposes.

The examination items used by TTM for breast masses included endocrino-logical triple images (pituitary, thyroid, and pancreas), abnormal auxiliary thermo-source, abnormal breast thermo-source, abnormal vascular thermo-source, abnormal nipple thermo-source, and abnormal areola of nipple thermo-source. The thermo-sources were analyzed according to their morphology, structure, depth, and temperature measured. The diagnostic standards for malignant breast tumor include asymmetry thermo-point, abnormal symmetry angiography, temperature deviation in the thermography, the positive thermography in the thermo-tomography, and thermo-point in the attenuation images [6,10,11].

### 23.5.3 Results

The correlation rates between TTM, MMT, ultrasonography, and pathological results in the 38 cases are shown in Table 23.4. There were 25 cases of malignancy and 13 cases of benignity from pathological tests. The correlation rate of the malignant and benign cases between TTM with pathological findings is (100%, 96%), respectively, which is superior to the correlation rate between MMT and ultrasound with pathological findings, (88.88, 63.63%) and (90.47, 63.63%).

Since endocrine-logical triple images are the most important in differential diagnosis of malignant and benign breast diseases, we study them in more detail. Figure 23.10 shows three signatures of the endocrino-logical triple images with the positive rate being higher in malignant cases than in benign cases.

Figure 23.11 and Figure 23.12 illustrate a side-by-side comparison between TTM and MMT in the diagnosis of benign and malignant tumors confirmed by pathological results obtained from surgery. The first case (Figure 23.11) shows benign bumps with abnormal breast thermo-source that was regular morphology with less vascular around the nipple and the areola of the nipple thermo-source. The second case (Figure 23.12) shows malignant bumps with abnormal breast thermo-source that was irregular morphology and more vascular, accompanied with swollen auxiliary lymph node. TTM evaluation results for the benign and malignant breast diseases are detailed in Table 23.5.

**TABLE 23.4** The Correlation Rate Between TTM, MMT, Ultrasound, and Pathological Results

Result	Pathology	TTM		MMT		Ultrasound	
		+	-	+	-	+	-
Malignant	25	24 (96)	1 (4)	16 (89)	2(11)	19 (91)	2 (9)
Benign	13	0	13 (100)	4 (36)	7 (64)	4(36)	7 (64)
Total	38	38		29		32	

Note: +indicates malignancy and –indicates benignity.

**FIGURE 23.11** (See color insert.) Benign bumps compared between TTM and MMT, confirmed by pathology. (a) TTM image of January 16, 2004 indicates the slices of abnormal thermo-source in the out-upper quadrant on left breast. These slices of thermo-source show the regular morphology and less vascular. (b) MMT image of January 16, 2004 shows a  $0.6 \times 0.5$  cm, clear-edged lump in the outboard on the left breast. (c) Pathology diagnosis of fatty tumor (©2005 IEEE).

**FIGURE 23.12** (See color insert.) Malignant bumps compared between TTM and MMT, confirmed by pathology. (a) TTM image of February 4, 2004 indicates the slices of abnormal breast thermo-source that were of irregular morphology, more vascular and higher heat values accompanied with swollen auxiliary lymph node. (b) MMT image taken of February 4, 2004 shows a blurred boundary mass with sand-grained calcification in the outboard on the right breast. (c) Pathology is infiltrated duct carcinoma (©2005 IEEE).

**TABLE 23.5** TTM Evaluation Results for the Benign and Malignant Breast Diseases

TTM evaluation standard	Result	Malignant patient/(%)	Benign patient/(%)
Endocrinological Triple graphs	Positive	24/(96)	5/(38)
	Negative	1/(4)	8/(62)
Abnormal breast heat source	Positive	25/(100)	12/(92.4)
	Negative	0	1/(7.6)
Abnormal axillaries heat source	Positive	15/(60)	8/(61.5)
	Negative	10/(40)	5/(38.5)
Abnormal vascular heat source	Positive	23/(92)	4/(30.7)
	Negative	2/(8)	9/(69.3)
Abnormal nipple heat source	Positive	20/(80)	2/(18.4)
	Negative	5/(20)	11/(84.6)
Abnormal areola heat source	Positive	12/(48)	3/(23.1)
	Negative	13/(52)	10/(76.9)

### 23.5.4 Discussion

Mammographic imaging using x-ray tubes with molybdenum, known for its low radiation, clear film and diagnostic accuracy, has been widely accepted by the doctors in the clinic. Unfortunately, it is rather difficult to obtain clear pictures with MMT detecting abnormalities of dense breasts in adolescent females due to its weak penetration. In addition, it is not easy to obtain correct diagnosis of breast cancer in its early stages. There is speculation limit in special areas such as laterosuperior quadrant of the breasts and axilla. There are also other disadvantages such as high cost and radiation damage, which result in limited usage. Ultrasonography is useful for tumor localization and identification of cystic tumors, but not good at differentiation between malignant and benign abnormalities.

Traditional infrared scanners are simple, harmless, and sensitive at the early stages of the tumor; however the poor penetration and localization, and temperatures assessment being limited on the body's surfaces result in a higher false-positive rate. Compared with the traditional infrared scanner, TTM is not only capable of measuring depths and temperature values of thermo-source which improves the specificity of assaying, it is also capable of evaluating the patients' general conditions including detecting metastasis of the lymph node in the auxiliary and superclavicular areas as well as other organs.

#### 23.5.4.1 The Mechanism of TTM Diagnostic Functions

Thermo-radiation that transferred heat energy from the inside to the surface of the body, reflects the subtle metabolism changes of living cells in the body. Using infrared scanners to receive signals from the heat radiation, TTM reconstructs a cell's metabolic extent map, which reflects the target organs or tissues by computerized processing of the data with specific regulations and measurements, and which measures the depths and temperature values of the thermo-source according to the thermo-deviations between normal and abnormal tissues, providing quantitative evidence for diagnosis [11].

Normal breasts are symmetrical, in which blood vessels are evenly distributed and metabolism of the acinic tissues is accordant with the adjacent structures. When cell differentiation is nearly mature, benign growth in the breasts is rather slow, resulting in little or no temperature difference between them. The metabolism of cancer cells is, on the other hand, very active, therefore its blood circulation is very rich. The cancer cells may develop several vasoactive agents such as bradykinin. The thermo energy transferred from the source of the dermis results in a high temperature area, that is, the thermo energy carried by the blood stream is transferred to the venous vessels in the superficial area and forms abnormal angio-images on the thermogram. There is no fat in the areola of nipple for heat isolation and the venous vessel plexus in the superficial area communicates with the ones in the deep area of the Haller's circle just behind the areola of nipple. Hence high temperature in the area shows significance in diagnosis of breast cancer.

### 23.5.5 The Value of TTM for Breast Diseases Differentiation

Jone reported that among more than 20,000 breast cancer cases from 1967 to 1972, the positive rates were 70% and nearly 90% in breast cancers in the I, II stages and III, IV stages, respectively [12]. The positive rate was 23% in 4,393 cases without symptoms with infrared scanner. Of the 1,028 positive cases, there were 2.4% cancer patients found using x-ray mammography, which was higher than the rate (0.7%) for the same test in the general survey of breast cancer [13]. In the meanwhile, at the 7th International Cancer Conference held by the American Cancer Association and the U.S. National Cancer Institute, Gerald D. Dodd reported that in a general survey of breast cancer for the female aged more than 40 years, 5% of those who were found have abnormal infrared results accounted for 15 to 20% of the total numbers, and to whom biopsy was suggested [14]. The study in this paper shows that TTM was found to be superior to MMT and ultrasonography for the detection of malignant cases from the benign cases.

Comparing TTM with other modern diagnostic techniques, TTM focuses on cell metabolism and provides both morphological evidence in anatomy and functional evidence in physiology, and reached concordance between the systematical examination and dynamic real-time examination. TTM was able to find more than 80% of micro-pathological changes in the tissues at its early stage [15,16]. Feig et al. [17] reported that infrared images are fourfold more sensitive than physical examination among 16,000 females who underwent general survey of breasts. Wallace [9] found that the detection rates were 0.27 and 1.9% in the x-ray mammography and infrared pictures, respectively. In 1980, Gautherie and Gros demonstrated that 1,245 females with all normal results including physical examination, mammogram, ultrasonography, and biopsy, but infrared confirmed more than one third of them as having breast cancer during the 5-year follow-up. It is concluded that breast thermography is not only an indicator of breast cancer, it may also detect breast abnormalities that develop quickly [18]. In 1983, Isard concluded that a combination of breast thermography and mammography raised the accuracy of diagnosis and reduced the amount of unnecessary surgery after exploring the characteristics of breast thermography and ultrasound [19]. As one of the functional diagnostic techniques, TTM is not only able to detect abnormal metabolism of the cells in the early stage with noninvasive techniques, it can also evaluate and analyze the depth, morphology and the thermo-values in real time. All but one in 38 cases coincided with the pathological results, and the diagnostic accuracy was 97.35%. It is concluded that TTM can be used to evaluate the sub-healthy conditions in humans as well as locate tumors at very early stages for the majority of breast diseases; especially those that develop very slowly, and is harmless to the human body, uses no environment pollutants.

## 23.6 Clinical Study on Using Thermal Texture Mapping in SARS Diagnosis

---

### 23.6.1 Introduction

Severe acute respiratory syndrome is a viral respiratory illness caused by a coronavirus, called SARS-associated coronavirus (SARS-CoV). Its first outbreak was recorded in Guang Dong Province of southern China in November 2002. In just a few months, the disease spread to 28 countries around the world. According to the World Health Organization (WHO) [20], during the SARS outbreak of 2003, a total of 8098 people worldwide became sick with SARS; of these, 774 died. This high infection rate and high fatality rate (1 out of 10.5 infected) are largely due to the limited understanding to the disease.

Scientists around the world have been trying to decode the genetic sequence of SARS in the hope of developing SARS antibody. However, till now, the most effective treatment still relies on good, intensive, and supportive care. Under this circumstance, early detection, early diagnosis, and immediate isolation are the keys to preventing another outbreak of SARS. Active image monitoring and analysis of the full clinical stages of illness are important for accurate diagnosis and treatment. Today, the standard diagnostic procedures are based on chest x-ray radiology exams and CT.

FIGURE 23.13 (See color insert.) SARS-CoV infection stages (©2005 IEEE).

In order to improve the process of diagnosing and monitoring SARS, a study has taken place in China that evaluates the clinical value of *infrared imaging* (IR) in the diagnosis of SARS. We use the term TTM [21] to represent the images captured from IR imaging.

Infrared imaging is a physiological test that measures the physiology of the blood flow and behavior of the nervous system by means of precise temperature measurement. Unlike imaging techniques such as x-ray radiology and CT that primarily provide information on the anatomical structures, IR imaging provides functional information not easily measured by other methods [20]. Compared to other imaging modalities, IR imaging is noninvasive, nonionizing, risk-free, patient-friendly, and inexpensive. It has the potential to provide more dynamic information of the patho-physiological abnormalities occurring in the human body at an early stage of disease development since the disease can affect a small area but can be fast growing making it appear as a high temperature spot in the TTM. The major shortcoming, however, is that it can only image the surface temperature and is principally a qualitative technique that can reveal little quantitative information about the size, shape, and depth information of the potential tumor. In this chapter, we present a new methodology which can estimate the depth information of lesion through surface temperature slicing. We evaluate the clinical value of IR imaging as a complementary tool to CT in SARS diagnosis.

Our study is conducted on a group of 111 patients that have been preconfirmed to be SARS patients by both clinical and laboratory diagnosis. Two imaging modalities, CT and IR, are used on each patient. The diagnostic results are cross-compared in order to study the clinical value of IR in the detection and monitoring of SARS.

### 23.6.2 The Pathology of SARS

Several studies have been conducted since SARS outbreak to help understand the pathology of SARS [22], which includes both parenchymal and interstitial abnormalities. Here, we divide the SARS infection process into three stages, interstitial infiltration, duplication, and macrophage increment.

In the early stage of SARS, the virus were mainly interstitial infiltrative as shown in Figure 23.13a. After penetrating into the alveoli, the SARS-CoV starts to duplicate itself in massive amount (Figure 23.13b) which eventually triggers the human immune system to react, causing proliferation of macrophages that could damage or block lung capillary, shown in Figure 23.13c.

In the following sections, we show how IR imaging can detect and monitor this abnormal metabolic activity of human body triggered by the invasion of SARS-CoV from different perspectives.

### 23.6.3 SARS Diagnosis Principles Using CT and TTM

It is considered, in general, that CT indications of SARS are in the density, appearance, and distribution of lesions. Density can show ground-glass opacity and consolidation. The shape of lesion could be focal, multi-focal, nodular, patchy, segmental, lobar, and in extensive conglomerated lesions. In addition, the lesions appear mostly in the lower lung areas and sub-pleural regions.

On the other hand, the TTM indications of SARS are in the discovery of abnormal heat patterns. This, combined with the depth estimation methodology discussed in Section 23.3.3, can be used to assist SARS

FIGURE 23.14 (See color insert.) TTM slicing of normal case (©2005 IEEE).

FIGURE 23.15 (See color insert.) TTM slicing of lung TB condition (©2005 IEEE).

FIGURE 23.16 (See color insert.) TTM slicing of SARS patient 1 (©2005 IEEE).

diagnosis. A study of the human cardiovascular system shows a couple of blood vessel concentration areas, among which the place where the jugular veins, carotid arteries, subclavian artery/vein meet is one of the most concentrated, and correspondingly, the hottest. We refer to this area as subclavian area. Therefore, when slicing the TTM of a normal patient, the subclavian area should first appear as white since it has a higher temperature than other parts of the human body. Otherwise, some abnormal metabolic activities must exist. Figure 23.14 shows the slicing results of the TTM of a normal patient. We observe that both the left and right subclavian areas appear as white earlier than the lung area. This rule of thumb applies to regular lung diseases as well. Figure 23.15 shows the slicing results of the TTM of a patient with lung TB condition. We can see that in the slicing process, the subclavian area is still the first one that goes white (the hottest).

Figure 23.16 and Figure 23.17 show the slicing results of TTMs from two SARS patients. In both cases, we observe that the subclavian areas do not show as white until the slicing causes portions of the lung area to be white. This indicates some serious abnormalities in the metabolic activity of the lung, which through clinical study, has been identified as one of the symptoms in the diagnosis of SARS.

**FIGURE 23.17** (See color insert.) TTM slicing of SARS patient 2 (©2005 IEEE).

At the initial and progress stages of SARS development, there is an increase in the thermal radiation of the lesions, and solid density heat structures normally appear over 3 cm deep from the surface of the skin that corresponds to the lesions found in CT.

In the later stages, the SARS patient may develop adult respiratory distress syndrome (ARDS), in which the main pathological abnormality is pulmonary edema. TTM would show the appearance of low thermal radiation zones and solid heat structures in lung areas, along with possible metabolic changes in the other organs.

At the recovery stage, there is normally decreased thermal radiation, with “cool zone” structures or “oval cold” solitary density structures that match lesions that display interstitial hyperplasia and compensatory emphysema, or cavities with purulence in the CT. TTM also shows decreased thermal radiation of the spleen, and increased thermal radiation of the spine.

### 23.6.4 Study Design

The study was conducted between March 10, 2003 and June 18, 2003 on 111 SARS patients (preconfirmed by both clinical and laboratory diagnosis) at Department of Communicable Diseases of Beijing You An Hospital, Beijing, China. All cases met the standard SARS diagnosis criteria set by the China Ministry of Health and the United States Center for Disease Control and Prevention (CDC). Among the 111 examined patients, 54 were male (24 cases between 12 and 30 years of age, 30 cases between 31 and 62 years of age, the average age being 34) and 57 were female (22 cases between 14 and 30 years of age, 35 cases between 31 and 68 years of age, the average age being 36). Out of the 111 cases, 98 claimed to have had close contact with another SARS patient or patients; their symptoms included fever (94.4%), nonproductive cough (92.7%), chest pain (83.3%), headache (55.6%), and Diarrhea (3%). Among the 111 patients, only 3 experienced no major symptoms. Laboratory tests of all the patients showed the following common symptoms (a) White blood cell count and lymphocyte count decreased during the earlier phases of the disease and (b) CD3, CD4, and CD8 T-cell counts were decreased — CD4 decreased most severely. T-cell counts were at their lowest 10 to 14 days after the symptoms started. The lower the T-cell count, the greater the severity of the SARS disease.

CT was performed for every patient upon admission into the hospital. Regular follow-up examinations were performed afterwards once every 4 to 6 days for a total of 80 to 90 days. TTM examinations were performed between May 19 and June 18, 2003 for all 111 cases. The CT was performed with a High-speed DX/I helical CT (HRCT) unit manufactured by GE Company with slice thickness and slice interval of 10 mm from lung apices to phrenic angles. The HRCT was performed with a 140 kV, 180 mA, with a slice thickness of 2 mm, and slice interval of 2 to 4 mm and bone algorithm reconstruction. The TTM examinations were performed in three positions; anterior, dorsal, and right lateral of body with a TSI-21M system manufactured by Bioyear Group, Inc. More than three senior radiologists and scientists assessed and reviewed all images.

### 23.6.5 Result Analysis and Performance Comparison

From the clinical study, we summarize our findings in the following three subsections.

### 23.6.5.1 Image Characterization of the Initial Stage of SARS

Small focal or multiple and extensive patches of infiltration density showed in 28 out of 111 cases, and among those 28, small focal opacity were more common (24/28, 85.7%). HRCT could show the lesion more clearly. It indicated that the focal ground glass opacity was common. TTM depicted abnormally increased thermal radiation and solitary density structures that correspond to lesions displayed in the HRCT, as well as an abnormal thermal radiation increase in the spleen and a decrease in the spine.

### 23.6.5.2 Imaging Characterization of the Progressive Stage of SARS

In this stage of SARS development, we found that (1) the uniform ground-glass-like density with ill-defined border and blood vessels (throughout the whole course of the continued follow-up observation) showed in 18 cases of 111 (16.2%), (2) the mainly ground-glass-like density with consolidation showed in 85 cases of 111 (76.6%), and (3) the mainly consolidation density with air-bronchogram image showed in 8 cases of 111 (7.2%).

Again, TTM dynamic manifestation depicted abnormally increased thermal radiation as well as solitary density structures that correspond to lesions displayed in the CT. The abnormal thermal radiation reached its highest level in the spleen. TTM also shows abnormality in the functions of other organs caused by SARS, or possibly by other, related or unrelated diseases.

### 23.6.5.3 Image Characterization of the Recovery Stage of SARS

In the *recovery stage* of SARS development, most of the patients exhibited normal images. Four (4) of the 111 cases showed pulmonary interstitial hyperplasia with multiple linear, reticular or honey-combed patterns. Some also displayed an increase in density of the subpleural arc line and thickened interlobular septa, or compensatory emphysema and reduced thoracic cage. Five (5) of the 111 cases showed focal or multi-cavity with purulence. TTM manifestations depicted abnormally low thermal radiation with “cool zone” structures that corresponded to lesions that displayed interstitial hyperplasia or compensatory emphysema, or “oval cold” solitary density structures that corresponded to cavities with purulent in the CT and radiograph. TTM continued to show a decrease in thermal radiation of the spleen and an increase in the thermal radiation of the spine.

### 23.6.5.4 Dynamic Evolution Imaging in SARS

Dynamic follow-up observations of changes in the images of SARS patients are indispensable, which is normally not necessary in other pneumonias. Imaging changes in SARS patients are not only dependent on the inherent development of the disease itself, but also on treatment management, treatment effects, age, previous health, etc. Among the 111 cases, some of the small patchy densities in the early stages progressed into extensive lesions in a very short time — roughly 24 to 48 h. Such dynamic change was largely consistent with worsening of the clinical condition. Diffusely scattered lesions in both lungs are suggestive of early ARDS. Progression from focal ground-glass-like density to extensive density with consolidation (CT) and appearance of low thermal radiation zone with abnormal solid density structure of heat (TTM) and signs of rapid development of the lesion are compatible with the clinical features of ARDS.

The decreased opacity showed resolution of the lesion, and eventual disappearance of low thermal radiation zone, along with decreased density of lesion structures and increased appearance of spine line and liver heat.

During the recovery stage, some patients displayed complicated pulmonary interstitial fibrosis or multiple abscess-like cavities. HRCT showed linear, reticular, and honeycomb-like densities. Radiographs cannot demonstrate detailed interstitial changes. Radiographic changes of lung markings are nonspecific for interstitial fibrosis. The low thermal radiation zone of TTM suggests the possibility of interstitial fibrosis.

**23.6.5.5 Comparison of the Usage of CT and TTM in SARS Diagnosis**

HRCT may demonstrate subtle focal lesions in the early stage of SARS, especially ground-glass-like density; corresponding TTM images may show solid density structures of lesions as well as other functional image information related with illness.

Figure 23.18 shows a side-by-side comparison of using TTM and CT in SARS diagnosis. The TTM slicing shows the abnormal heat pattern with the depth of heat source 6 cm from skin surface. In addition, the subclavian area has a lower temperature than that of the right lung since the lower part of the right lung becomes white first. The CT image of April 26, 2003 showed the right lung lesion of SARS in its progress stage. The CT image of May 23, 2003 showed right lung lesion of SARS in its recovery stage. TTM image of May 23, 2003 indicates the abnormal heat pattern of lower right lung lesion which is confirmed by the CT image of the same date.

During the treatment of SARS, it is necessary to monitor the chest condition, such as the distribution and extent of the lesion and the effect of treatment. Following the initial stage of the disease, TTM could become the main imaging modality of examination of SARS since it can show the general manifestation of the disease. In addition, it is convenient, less expensive, and requires less exposure to potentially harmful radiation. During the recovery stage, if there is any change towards possible pulmonary interstitial hyperplasia, HRCT and TTM should be used to reveal the details of the interstitial and functional low-thermal radiation zone. The different features of these two imaging modalities are summarized in Table 23.6.

**FIGURE 23.18** (See color insert.) Comparison between CT and TTM in SARS diagnosis — TTM image of May 23, 2003 indicates the abnormal heat pattern of lower right lung lesion which is confirmed by the CT image of the same date. *First row:* TTM slicing shows the abnormal heat pattern with the depth of heat source 6 cm from skin surface; in addition, the subclavian area has a lower temperature than that of the right lung. *Second row:* (a) CT image of April 26, 2003 showed right lung lesion of SARS progress stage; (b) CT image of May 23, 2003 showed right lung lesion of SARS recovery stage (©2005 IEEE).

**TABLE 23.6** Performance  
Comparison between CT and TTM

	CT	TTM
Radiation	Yes	No
Protection	Difficult	Easy
Exam time	25 min	5 min
Cost	High	Low
Environment risk	Yes	No
Mobility	Worst	Best
Consumption	30 KW	0.3 KW

The TTM, as a functional imaging modality, is able to quickly examine and assess the position, morphology, and progress of SARS lesions, in the meantime effectively monitoring treatment and patient recovery by providing information regarding the functional condition of the liver, spleen, kidney, and other organs.

The TTM can be used as first line imaging system for SARS screening, followed by CT, and TTM to carry out further differential diagnosis, including full course treatment monitoring. This combination of the two imaging systems should be the most beneficial for future prevention and treatment of SARS.

## 23.7 Study of Trilogy-Imaging Characteristics on TTM and Its Relationship with Malignancies

---

### 23.7.1 Introduction

The human body is a heat-radiant source under normal condition with balanced metabolism, and the heat is transmitted from the within the body to the surface. Once disease occurs at a site, such as a tumor, an inflammation, or hyper-functionalism and hypo-functionalism, the normal metabolism of regional cells in this site will change, reflected as the change of the heat radiance value. TTM can receive ultra-red radiance signal transmitted from cells during metabolism, and examine the exact intensity of different sites. The depth of abnormal heat foci can also be localized. See Section 23.3 for detail.

During the clinical study of the TTM technology, we found that independent heat foci can be discovered in the head (equivalent to occipital tuberosity), the neck (equivalent to thyroid gland), and the upper abdomen (equivalent to pancreas) in most of the patients with malignancies (these abnormal heat foci are not obvious in senile and advanced malignancy patients). We refer to this phenomenon as the *trilogy-imaging characteristics on TTM*. This phenomenon also exists in a small set of normal populations, and surprisingly, in this small set, 60% of the people have a family history of malignancy in direct relatives.

Great interest has been generated in the study of correlation between the abnormal heat foci (trilogy-imaging with TTM) and tumor. In our research, we examined 90 cancer patients and 32 normal controls with TTM. Their imaging characteristics were compared to elucidate the relationship between cancer patients and trilogy-imaging characteristics on TTM. Based on these study results, we can explore the mechanism of trilogy-imaging characteristics on TTM in cancer patients, and provide theoretic basis for further diagnosis.

### 23.7.2 The Neuro-Endocrine–Immune Theory

Due to its origin from neuro-endocrine system [23–27], we try to discuss the characteristics of trilogy-imaging on the basis of Neuro-Endocrine–Immune theory.

In 1977, Besedovsky first advised the Neuro-Endocrine–Immune network hypothesis. In the last two decades, many studies were performed at the *in vivo*, cellular and molecular levels; and results have shown the effectiveness of neurotransmitters and hormone molecules on the modulation of the immune system. On the other hand, the immune cell can produce neuro-endocrine hormone through some cytokines, which indicates that the neuro-endocrine and immune system constitutes a complex network, and the latter plays an important role in the regulation of normal activities of the whole body. However, can this theory explain the phenomenon of abnormal heat foci on TTM in the patients with malignancies?

Studies show that, in the status of malignancies, there are two kinds of antitumor immune responses, including specific ones and nonspecific ones, and many cytokines are involved in this process. At the same time, circulating cytokines can enter the brain through the third cerebral ventricle, binding the correspondent receptors, and exerting its effect on the central nervous system (CNS), to stimulate the production and release of neuropeptide, such as dopamine (DA) and epinephrine, as well as other local cytokines. In addition, the second messenger, such as cAMP, IP3, and DAG can be activated by cytokines and antigens. All the above show that cytokines can work on CNS, and indirectly affect the release of specific neuro-hormone (TRH, CRH, etc.) on pituitary gland, and finally regulate the endocrine system, manifested by

the abnormal heat foci in the occipital tuberosity (hypothalamus), thyroidal gland and pancreas on TTM imaging. The compromised immune function in the senile and patients with advanced cancer can explain the unobvious heat foci in this population.

The exchange of the message in the above mentioned neuro-endocrine-immune network constitutes a regulative circuit: antigens (including tumor antigens) stimulate the release of the immune cytokines, and the latter work on the distant neuro-endocrine structure, then feed back to the CNS. The CNS can regulate the peripheral immune system through the release of hormones, peripheral neurotransmitters, and neuropeptides. In the animal models, the electronic activities and hormone shifting rate in neuro-endocrine system changes greatly after the activation of the immune system by antigen. This result provides strong support for the theory, that the imaging of TTM can confirm the modulation of neuro-endocrine-immune network and stress status indirectly.

### 23.7.3 Clinical Study of Correlation Between Trilogy-Imaging of TTM and Malignancies

#### 23.7.3.1 Experiment 1

This study selected 90 cancer patients, aged between 35 and 75. Among them, 28 were diagnosed as having digestive tract cancers, 43 with breast cancer, 17 with lung cancer, and 2 with prostate cancer. All patients are from either Rui-Jin Hospital or Rui-Mei Health Center in Shanghai, China. To form the control data, 32 healthy volunteers from Rui-Mei Health Center, aged between 25 and 51, were chosen.

All the patients were asked to take off their clothes and rest in the room of examination of temperature 22 to 25° for heat balance. The TTM technique (TSI-2 type system, made in China) was then used to capture the thermal image from the standard position. Appropriate variables such as temperature scale, lens, and temperature window were set and topographic analysis was performed. The CES2000 software was used for statistical analysis.

Among the 90 cancer patients, 86 were diagnosed to have trilogy-imaging characteristics on TTM. Two patients with advanced cancer and 2 senile cancer patients did not have that characteristic. Table 23.7 shows the detailed statistics. TTM (+) is used to denote patients with trilogy imaging on TTM, and TTM (-) those without trilogy imaging on TTM.

We performed the chi-square test on the data. Statistical significance was reached ( $P = 0.0000$ ), and  $H_0$  was refused if  $\alpha = 0.0500$  is assumed. The percentage of the characteristics of trilogy imaging on TTM is higher in the cancer patients than in normal population.

In the 32 normal control patients, 9 volunteers had trilogy characteristic on TTM, among them, 6 (more than 66%) had cancer family history in direct relatives. Detailed statistics are listed in the following table.

	TTM (+)	TTM (-)
With cancer family history	6	3
Without cancer family history	3	20

We also performed chi-square test on the data. Statistical significance was reached ( $P = 0.0003$ ), and  $H_0$  was refused if  $\alpha = 0.0500$  is assumed. The percentage of the characteristics of trilogy imaging on TTM is higher in the people with a family history of cancer than those without.

**TABLE 23.7** Chi-Square Value (Pearson Unadjusted) = 62.2843,  $P = 0.0000$

	TTM(+)	TTM(-)
Cancer patients	86	4
Normal population	9	23

**TABLE 23.8** TTM and Chi-Square Test Results

Results	TTM (+)	TTM (-)
Abnormal thyroid function (↑ or ↓)	1	0
Normal thyroid function	8	2

**TABLE 23.9** The TTM Trilogy Imaging Results of Six SLE Patients

Results	TTM (+)	TTM (-)
6 SLE Patients	0	6

**23.7.3.2 Experiment 2 — Study of Correlation between Thyroid Function and Abnormal Heat Foci in Neck**

TTM examination were received by histology-diagnosed cancer patients (4 males and 7 females, aged 38 to 71) received TTM examination. Among them, 3 were diagnosed with gastric and colon-rectal cancer, 6 with breast cancer, and 2 with lung cancer. Trilogy imaging occurs in 9 out of 11 (81.82%) cancer patients.

Thyroid examination was performed on the patients by isotope scan. Thyroid function including T3, T4, FT3, FT4 was assayed at the same time. Detailed statistics are listed in Table 23.8. The chi-square test is performed on the data. Correlation analysis of cross table data shows that  $P = 1.0000$ , and  $H_0$  is not refused according to  $\alpha = 0.0500$ , which indicates that abnormal heat foci might not be related to thyroid function.

**23.7.3.3 Experiment 3 — Correlation Study of Autoimmune Diseases and Trilogy Imaging Characteristics**

Totally 6 clear diagnosed SLE patients (all female, aged 22 to 43 [mean 29]) received TTM examination on March 2004. There is no relationship between the trilogy characteristics on TTM and the autoimmune disease. But these patients all received high dose corticoids, which may affect the results of TTM. The clinical data of previously untreated autoimmune disease patients will be collected for further research. Detailed statistical results are shown in Table 23.9.

**23.8 Discussion**

Through various clinical studies, we found that most of the patients with malignant cancers were related to trilogy-imaging characteristics on TTM (corresponding to occipital tuberosity in the head, thyroid gland in the neck, and pancreas in the upper abdomen). Interesting questions are raised, for example, are these characteristics representing function abnormality of these specific tissue or organ? Is there any theoretical basis behind the abnormal behavior? Based on their correspondent anatomic sites, we think it is associated with hypothalamus, thyroid gland, and pancreas.

We have conducted three clinical studies. Statistical results show that there is a high correlation between the trilogy-imaging characteristics of TTM and the malignancies. In the meanwhile, we also found, from the first clinical study, that a lot of the normal volunteers also manifest trilogy characteristics on TTM, and above 60% of these volunteers have direct family history in close relatives. How can we explain this phenomenon given that no clinical malignant parameters are found in these patients? Study shows that malignancy is a kind of genetic disease, determined by both genetic and environmental factors. The volunteers with family history may carry potential abnormal genes, which determines the evolution of malignant cells, and the abnormal protein expressed by these genes can induce immune response that further affects the neuro-endocrine system. Due to the long process of the formation and development

of the tumor, the neuro-endocrine-immune network was already in stress status, hence forming the characteristic change of TTM imaging. Theoretically, specific antitumor immune response works in the early or even primitive period of the tumor development stage. We can discover the occipital tuberosity, cervical, and mid- or para-abdominal abnormal heat foci in the very early stage of the tumor, which will help us in the early diagnosis of the tumor if the results are proved by prospective studies.

Many studies have shown the effect of cytokines on neurohypothalamus-endocrine system. From the second clinical study, we found that the abnormal heat foci in the neck may not originate from the thyroid, and that the foci in abdomen may not originate from pancreas.

In addition, we have studied the manifestation of TTM trilogy imaging in cancer patients, and discovered that, in part of the patients, the abnormal heat foci present in a node form and concatenate with each other. This phenomenon also occurs in the unfixed site in chest.

According to the correspondent anatomic site of abnormal heat foci on TTM, we reviewed many references and propose a new possible hypothesis: *A tetralogy imaging originates from hypothalamus and cervical, thoracic and abdominal sympathetic ganglia*. This hypothesis is based on the following four arguments:

1. According to the neuro-endocrine-immune theory, hypothalamus can regulate sympathetic and parasympathetic nerve (the highest center of vegetable nerve), besides the modulation of the secretion of hormones of pituitary gland.
2. Cytokines can activate hypothalamus platform, especially hypothalamus-pituitary body-adrenal gland (HPA) axis (through IL-1).
3. Sympathetic trunk was distributed both on the neck and along the spine: cervical sympathetic trunk was localized posterior to cervical vessel sheath, anterior to transverse process; thoracic and lumbar sympathetic ganglia was localized along the spine. They are all activated by norepinephrine and other transmitters such as neuropeptide. Norepinephrine is mainly released from the sympathetic nerve end; it plays an important role on integrating the neuro-endocrine function and visceral automatic nerve reaction.
4. There is clear correspondence among the sites of four abnormal heat foci and the sites of hypothalamus, cervical sympathetic trunk and thoracic, lumbar sympathetic ganglia.

These imply that TTM signal abnormality was caused by hypothalamus, cervical sympathetic trunk and thoracic and lumbar sympathetic ganglia dysfunction, rather than hypothalamus-thyroid gland-pancreas platform we know before. This hypothesis is in consistence with the neuro-endocrine-immune theory. In immune mechanism, cytokines can affect hypothalamus, and play another important role, regulation of vegetable nerve function besides affecting endocrine. Hence, sympathetic trunk function is changed, manifesting of signal abnormality of malignancy platform on TTM. In animal models, immune response was first triggered by no toxic, no infectant and no newborn antigen. Results also showed that their endocrine system, automatic nerve system and catecholamine shifting rate were changed after the activation of the immune system.

## 23.9 Summary, Conclusions, and Recommendations

---

After ten years of R&D work, the TTM medical evaluation technology has gone through different phases; from merely a lab experiment, accepted by society and finally enters the initial stage of mass production. At the dawn of the new century, TTM technology will change the conventional model of medicine and lead human health to a completely new phase, the medical prediction phase. During this phase, efforts are dedicated to a new model of medicine, that is, active prediction and protection compared to conventional passive treatment, such that unhealthy elements can be restrained before the onset of diseases.

The TTM technique and the resulting apparatus have been patented [27]. Clinical study has shown increased sensitivity and specificity with the use of this method. The concept has been validated in China for several applications, including breast cancer detection, and ovarian cancer detection. About 400,000

patients were scanned using the TTM system in 5 years. Among them, 50,000 patients underwent breast scan. There are 103 breast cancer cases detected by TTM which were proved by biopsy. Among these 103 cases, 92 cases also went through mammography. Mammography missed 6 out of these 92 cases. Two of the missed tumor size is 2 mm. The concept is also in the process of validation in the United States/Canada, including the Ville Marie Breast Cancer Center in Canada (TTM's diagnosis agrees with Center's diagnosis on 198 cases out of 200 testing images), Elliott Mastology Center at Baton Rouge, LA, and NIH (Kaposi Sarcoma/Angiogenesis).

Different from routine biochemical assays and imaging examinations, TTM is convenient, nontraumatic, and economical. At the same time, it can provide additional information of the status of immune function, in addition to the exact tumor image. The tumor platform of TTM is especially helpful to the patients with occulting history or susceptible to malignancy, probing for a health examination, and disease screening.

In addition, initial clinical studies also make us believe that tetralogy imaging may be more reasonable according to the nature of the cancer, which is caused by the activation of hypothalamus, cervical, thoracic, and abdominal sympathetic ganglia. Further research is needed for more accurate validation and quantification.

## Acknowledgments

The authors are grateful to colleagues and many contributors for the very instructive suggestions and support of the clinical study which led to the much improved quality of the chapter.

### 24.1 Introduction

---

The SARS is a new potentially fatal infectious viral respiratory illness caused by a novel coronavirus, named the SARS-associated coronavirus (SARS-CoV) (Ksiazek, 2003; Peris, 2003; Rota, 2003; de Jong, 1997). The main symptoms of SARS (Ksiazek, 2003) are high fever, dry cough, shortness of breath, and breathing difficulties. The first SARS outbreak occurred in Guangdong Province, China in November 2002. Aided by international air travel, it had spread worldwide by late February 2003. The first outbreak of SARS officially ended when World Health Organization (WHO) announced that the last human-to-human transmission of the coronavirus had been broken on June 5, 2003. From the data compiled by WHO in August 2003, there were 8437 cases of SARS in 29 countries of which 813 were fatal (CDC, 2004). Singapore is one of the more severely affected countries, which includes China (including Hong Kong and Taiwan), Canada, and Vietnam. The economic cost of the SARS outbreak has been high with disruption of commerce and

health care. With the diminished number of overseas travelers, the tourism and airline industries were particularly affected.

Although SARS has been contained, there is a constant fear of reemergence of the virus. It has been proposed that the imposed ban on the exotic-animals trade is one of the main reasons that SARS has failed to stage a significant resurgence still April 2004 (Pottinger, 2004). Other reasons why the disease did not return in the winter of 2004 are open to debate. This winter, just four people were diagnosed with SARS, all in Guangdong province. By May 5, 2004 only nine more people (with one dead) were diagnosed with SARS in Beijing and Anhui. There has been a vast improvement in China's response to the recent SARS outbreak and at the time of writing, there has not been community spread of the disease. Despite intense research, the behavior of the SARS coronavirus is still unpredictable and the threat of SARS resurfacing and causing an epidemic still remains.

Officials at the WHO therefore worry that the disease still has the potential to resurface and create a health crisis as it did in 2003, when it caused serious atypical pneumonia killing 813 and disrupting commerce and health care in cities from Hong Kong to Hanoi and Singapore, Toronto to Taipei. For example, the diminished number of overseas travelers, the reduced number of airline flights, and other factors significantly damaged the relevant sectors, such as the tourism and airline industries in many countries.

In short, speculation that the virus had lain dormant in human during the warm months of summer and autumn, waiting to wreak havoc when temperatures dropped, appears to have been incorrect. Exactly how the virus burrowed itself out during the summer of 2003 remains a mystery. Bold policy measures, including travel alerts, quarantines, and public-hygiene campaigns, were critical in containing the disease and saving lives. There is still no cure or vaccines for SARS and the best that can be done to prevent another SARS outbreak is early detection to prevent the local and international spread of the SARS virus. Constant vigilance must be maintained. It is therefore important to have a reliable mass screening method for potential SARS patients at airports, seaports, immigration checkpoints, and hospitals.

It is thus important for the use of screening process at airports, seaports, immigration checkpoints, and hospitals for reliable mass blind screening of potential fever subjects, as these are crowded, mission critical facilities, and unfortunately terrific amplifiers for SARS transmission.

The cardinal symptom of SARS is fever. Because of the ability of infrared (IR) imaging systems to generate thermograms and measure temperature, it has been proposed that the use of these systems for the detection of elevated body temperature would be an efficient and accurate method for mass blind screening for potential SARS infected persons. The quality of the IR system depends on how well it fulfills its intended purpose, understanding of its limitation and degree of error involved. Some sources of uncertainty include drift, ambient temperature, humidity range, sunlight, nearby electrical sources, lighting, target distance, response time, etc. These variables may potentially cause both false negative and false positive readings without any outward indication that the data are flawed (Airport, 2003; Blackwell, 2003; Canadian, 2003).

The IR imager measures only the skin temperature. The skin temperature is lower than the normal core body temperature (98.6°F/36.9°C), due to well-studied heat evaporation, conduction, and convection principles (Ng and Sudharsan, 2001). It is thus important to establish an appropriate temperature baseline at the most practical site (such as forehead, eyes, or whole face, etc.) as the upper limit of normal for a healthy person. A temperature reading above the cut-off "baseline" reading signals a potential fever. When an elevated temperature is detected, the subject's body temperature is confirmed with an oral or aural thermometer. A truly febrile subject will be sent for medical assessment. Used in this manner, IR imagers can be the first line of defense in SARS screening.

## 24.2 Physics of Thermal Radiation Theory

---

Any object whose temperature is above absolute zero Kelvin emits radiation at a particular rate and with a distribution of wavelengths. This wavelength distribution is dependent on the temperature of the object

and its spectral emissivity,  $\varepsilon(\lambda)$ . The spectral emissivity, which may also be considered as the radiation efficiency at a given wavelength, is in turn characterized by the radiation emission efficiency based on whether the body is a blackbody, greybody, or selective radiators. The blackbody is an ideal body. It is a perfect absorber that absorbs all incident radiation and is conversely a perfect radiator. This means that a blackbody absorbs and emits energy to the maximum that is theoretically possible at a given temperature. Within a given wavelength:

- $\varepsilon = 1$  for blackbody
- $\varepsilon = \text{constant} < 1$  for greybody
- $0 \leq \varepsilon \leq 1$  for selective radiator

The radiative power (or energy) and its wavelength distribution are given by Planck radiation law (Burnay et al., 1988):

$$W(\lambda, T) = \frac{2\pi hc^2}{\lambda^4} \left[ \exp\left(\frac{hc}{\lambda kT}\right) - 1 \right]^{-1} \text{ Wcm}^{-2}\mu\text{m}^{-1} \quad (24.1)$$

or in number of photons emitted:

$$P(\lambda, T) = \frac{2\pi c}{\lambda^4} \left[ \exp\left(\frac{hc}{\lambda kT}\right) - 1 \right]^{-1} \text{ photons sec}^{-1} \text{ cm}^{-2}\mu\text{m}^{-1} \quad (24.2)$$

where

- $h$  (Planck's constant) =  $6.6256 \times 10^{-34}$  Jsec  
 $c$  (velocity of light in vacuum) =  $2.9979 \times 10^8$  msec<sup>-1</sup>

 $\lambda$  = wavelength in  $\mu\text{m}$   
 $T$  = temperature in K.

While infrared radiation is invisible to human eye, it can be detected and displayed by special IR cameras. These cameras detect the invisible infrared radiation emitted by an object and convert it to a monochrome or multicolored image on a monitor screen wherein the various shades or colors represent the thermal patterns across the surface of the object. The thermal imager is coupled with computer software, for the interpretation of the infrared images (thermal maps). Figure 24.1 illustrates an example of normal and febrile temperature profiles from a thermal imager (Flir, 2004). Temperature readings are also registered.

In general, thermal imagers offer an excellent means of making a qualitative determination of surface temperature, but there are many difficulties in obtaining an absolute measurement. The skin is the largest organ in the human body and helps to maintain the thermal equilibrium of the body and the environment through heat transfer processes. The study of the heat exchange processes of the body from the deep tissues to the skin and subsequently to the environment can provide information on pathology (Ng and Sudharsan, 2001; Ng and Chua, 2002; Ng and Kaw, 2004a,b).

## 24.3 Pathophysiology

### 24.3.1 Body vs. Skin Temperature

Heat is generated from energy released secondary to metabolic processes that are constantly taking place in the body. For example, the enthalpy change of reaction for average mixed foodstuffs (with balanced stoichiometric reaction) is  $-320$  kcal/mole.

**FIGURE 24.1** (See color insert following page 29-16.) Examples of temperature profiles using thermal imager with temperature readings. (Taken from FLIR Systems <http://www.flir.com>, accessed November, 2004. With permission.)

Part of this energy is conserved as transformation and the rest is released as heat that accumulates within the body, causing its temperature to rise. Following Newton's law of cooling, this heat can be readily dissipated into the environment as long as it is cooler than the body temperature. The body temperature is thus the difference between the amount of heat produced by metabolism within the body and the amount of heat lost to external environment (Ng and Sudharsan, 2004).

Heat generated by the body is first transported to the skin before dissipation into the environment (Figure 24.2). The skin has its own temperature, which will be termed skin temperature in this chapter. Temperature from different sites on the skin surface varies. This in turn varies from the core body temperature. The normal body temperature ranges from 36 to 38°C whilst the mean skin temperature is 33°C. The core temperature refers to the temperature within deep tissue (Houdas and Ring, 1982). It is relatively constant, despite changes in environmental conditions and the degree of physical activity. On the contrary, skin temperature fluctuates and is a function of the amount of heat flow into it. Therefore it is generally agreed that the core temperature is a better indicator of body temperature. However, the measurement of core temperature is generally more difficult and time consuming. Hence, it is not practical for mass-screening purposes. Some of the sites for body temperature measurement are:

1. Oral
2. Aural or Tympanic membrane (Core)
3. Rectal (Core)
4. Axillary (Core)
5. Esophageal (Core)
6. Pulmonary artery (Core)
7. Urinary bladder (Core)

### 24.3.2 Human Body Heat Exchange

Heat produced by the human body through metabolism is transported from the body to the skin and is subsequently dissipated to the environment via conduction, convection, radiation, and evaporation (Houdas and Ring, 1982). These methods of heat loss can be classified as “Dry” heat exchange with the environment. Within the body, heat is transferred by conduction through the tissue and convection through blood. Convection via the blood is a very efficient component of heat transfer within the body, thus making skin temperature predominantly determined by the blood flow to the skin. Apart from “Dry” heat exchange, heat is also lost by evaporation of sweat and respiration. Evaporation of sweat removes heat from the body. This is a surface process in which only the portion of sweat evaporated results in heat loss from the body. Evaporation also takes place in the respiratory tract. However, the heat loss from this site is minimal and insignificant. Figure 24.2 illustrates the heat exchange processes of the body, which will affect the skin temperature. The body and environment eventually reaches equilibrium. Nonetheless, there are pathological processes such as inflammation, tumors, etc. that can cause changes in the heat flux. Invasion of pyrogens (of which the SARS coronavirus is an example) can also cause the body temperature to change. This is discussed in the next section. In fact, temperature change is one of the earliest symptoms of a pathological process. This may be detected via the patterns produced on thermography.

### 24.3.3 Fever

Blatties (1998) defines fever specifically as the elevation of the core body temperature exhibited by most species in response to invasion by infectious agents. Fever is a non-systemic reaction designed to combat the effects of invading pathogens. A fever is the primary host defense response to restore health to the afflicted host. High fevers destroy temperature-sensitive enzymes and proteins and cause increase in ventilation, perspiration, and blood flow to the skin. A fever should be distinguished from hyperthermia. During hyperthermia, the rise in body temperature is the consequence of the passive gain of heat in excess of the capability of active thermolytic processes. The rise in body temperature during a fever is the result of the activation of thermogenic effectors. Many different substances (pyrogens) can cause fever. The consequence of infection and fever is a hot flushed skin and increased fluid loss.

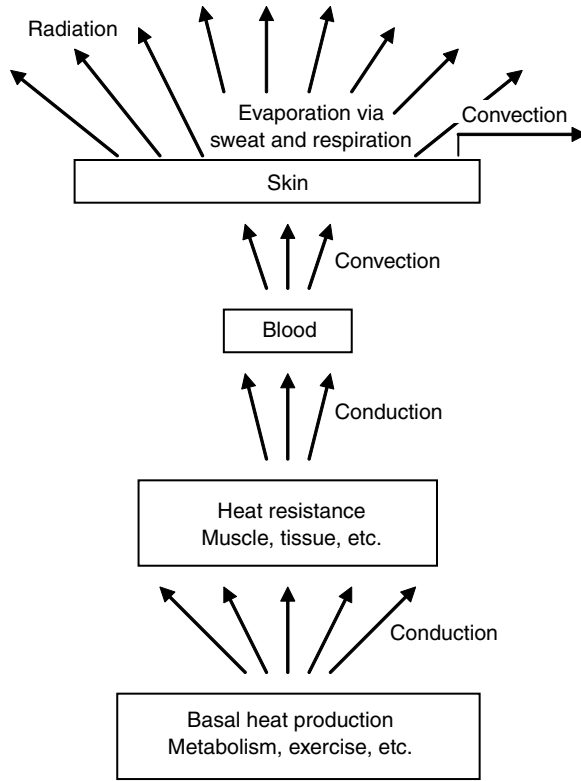

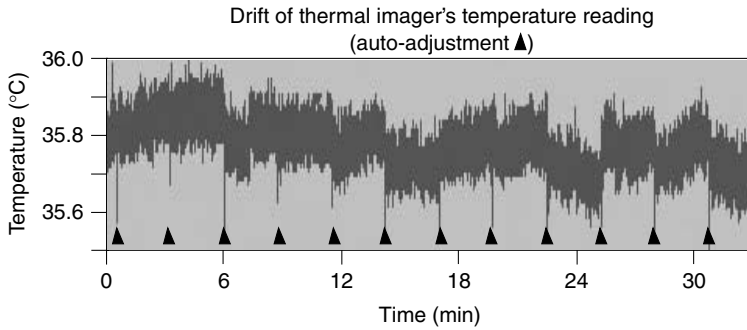

FIGURE 24.2 Human body heat exchange.

### 24.3.4 Infrared Thermography

As a diagnostic tool, thermography has several advantages in clinical use (Ng and Sudharsan, 2000). First, the physiological test equipment is completely passive, emits no harmful radiation, can be sited at a distance from the subject, and is noninvasive. Second, the test is ideal for detecting hot and cold spots, or areas of different emissivities on the skin surface since humans radiate infrared energy very efficiently. The emissivity of human skin is nearly 1.0. Third, the data collected can be recorded on photographic media, videotape, or sent to a computer for post processing. Finally, the equipment is highly portable, fully self-contained, and can be set up within minutes. It does not need any sources of illumination, thus making day and night imaging possible.

Although IR systems have many advantages for temperature screening, other than its cost, there are many variables that can affect its accuracy (Ng and Sudharsan, 2000). Ideally, the thermal imager should be operated in a stable indoor environment with stability of the operating ambient conditions within  $\pm 1^{\circ}\text{C}$ . The thermal imager is ideally intended to operate in a stable indoor environment with operating ambient conditions and stability of  $\pm 1^{\circ}\text{C}$ . The relative humidity range for the operating temperature range should also be from 40 to 75%. Environmental infrared sources such as sunlight, nearby electrical sources, and lighting can affect the accuracy of IR systems and should be minimized. The target should be located in an area free from draft and direct airflow.

The accuracy of the thermal imager is highly dependent on the skill and knowledge of the operator (Spring, 2003). Mishandling of the equipment will result in erroneous data. It is also important to understand that each make and model of IR equipment has different specifications and accuracies that can affect observed temperatures. Various scanners have different drift between self-corrections (Figure 24.3), uniformity within the field of view, minimum detectable temperature difference, error and stability of

**FIGURE 24.3** An example of the drift of a typical thermal imager's temperature reading between auto-adjustments. (Taken from Standards Technical Reference for *Thermal Imagers for Human Temperature Screening Part I: Requirements and Test Methods*, 2003. TR 15-1, Spring Singapore. ISBN 9971-67-963-9. With permission.)

**FIGURE 24.4** An example of the stability of a typical thermal imager's temperature reading. With permission.)

threshold temperature (Figure 24.4), distance effect and minimum number of detector pixels in addition to different environmental requirements and subject conditions. For rapid and effective screening of a large number of people, it is essential that the thermal imager be capable of operating in a real time processing mode.

Disease processes can produce significant and unpredictable changes in body temperatures. Circulatory problems, previous injuries, and alcohol consumption can reduce body surface temperature. On the other hand, skin temperature can be increased by stress, physical exertion, the use of stimulants such as caffeine and nicotine, and inflammation secondary to trauma, or even sunburn. Heavy makeup, hormone replacement therapy, pregnancy and menstruation, can affect also skin temperature.

## 24.4 Study Design

The study was conducted in the Emergency Department of Tan Tock Seng Hospital (TTSH), the designated SARS hospital in Singapore and the Singapore Civil Defense Force Academy (SCDF). The total blind sample size collected was 502 with 85 febrile and 417 normal cases. Temperature readings were taken from the eye region (Ng and Kaw, 2004a,b). The breakdown of the sample is shown in Table 24.1.

The imager used by for the study in TTSH and SCDF was a handheld ThermaCAM S60 Flir system (Flir, 2004). The focal length from the subject to scanner was fixed at 2 m. The average temperature of the skin surface was measured from the field of view of the thermal imager with an appropriate adjustment for skin emissivity. Human skin emissivity may vary from site to site ranging from 0.94 to 0.99. Averaged

**TABLE 24.1** The Sample Sizes for Eye Region

aural temperature readings of both left and right ears were also taken using Braun Thermoscan IRT 3520+ (Ear, 2004). Thermal images from the TTSH (obtained over 2 weeks) sample were later processed using the ThermaCam Researcher 2002, computer software (Flir system, 2004). The following spots were logged and analyzed from the frontal profiles:

- Forehead
- Eye region
- Average cheeks
- Nose
- Mouth (closed)
- Average temple

Figure 24.5 shows an example of a processed thermal image of the frontal profile. A total of 187 (subjects) temperature readings were extracted from these spots. Among which, 21 were febrile cases and 166 were normal cases. This set of readings will be referred as data set E in this paper. The images were further processed to obtain readings from both frontal and side profiles from some of the subjects. Sixty-five sets of temperature readings with 10 febrile and 55 normal cases were extracted. This set of readings is referred to as data set F in the chapter. Figure 24.5 and Figure 24.6 presents an example of the processed thermal images of both frontal and side (left) profiles from the same subject. The following spots were logged from the subjects with frontal and side profiles:

- Forehead
- Eye region
- Average cheeks
- Nose

- Mouth (closed)
- Average temple
- Side face
- Ears
- Side temple

## 24.5 Linear Regression Analysis

Linear regression analysis (Dupont, 2002; Golberg, 2004) is a statistical method for obtaining the unique line that best fits a set of data points. The line of best fit is also known as the linear regression line. It uses the concept of “least squares,” which minimizes the sum of square of the residuals or errors. S-Plus (version 6.1) software (2004) was used to perform the regression analysis. Different combinations of blind data from TTSH — 2 weeks, 2 days, and 3 days and SCDF were used for the regression analysis in order to increase the total sample size for comprehensive analysis. The mass screened data were given an alphabetical representation for easy reference and is summarized in Table 24.2. These alphabetical representations will be used synonymously with the actual data name in this chapter. For example, ABCD represents the combination of TTSH (2 weeks), TTSH (2 days), SCDF, and TTSH (3 days).

A linear regression analysis has two types of variable: dependent and independent variables. The independent variable used in the analysis is skin temperature (detected by the thermal imager) and the dependent variable is the core temperature (taken from the ear temperature readings). Figure 24.7 shows the regression line obtained using data set ABCD. The skin temperatures used here were extracted from the inner eye region.

Using the S-Plus software, a linear regression equation  $y = \alpha + \beta x$  is generated where  $\alpha$  is the intercept and  $\beta$  is the slope of the line. The linear regression equation in this case is  $y = 24.0922 + 0.3695x$ . The result of main interest here is the slope of the line  $\beta$ , which is 0.3695. This parameter indicates the strength of relationship between the skin temperature and body temperature and can be used to predict one variable

FIGURE 24.6 (See color insert.) Processed thermal images of the side profile.

TABLE 24.2 Alphabetical Representations of Data

Data	Alphabetical representation
TTSH (2 weeks)	A
TTSH (2 days)	B
SCDF	C
TTSH (3 days)	D

from another. While the regression line explains a proportion of the variability in the dependent variable ( $y$ ), the residuals indicate the amount of unexplained variability. The residual is thus a good indicator of the goodness of fit. A more general way of assessing the goodness of fit is to consider the proportion of the total variation explained by the model. This is usually done by considering the sum of squares explained by the regression as a percentage of the total sum of squares. This value is called  $R^2$  and it assesses how well the model fits the overall data.  $R^2$  has a value from 1 to 0 and a low value of  $R^2$  indicates that even if a significant slope exists, the majority of the variability in body temperature is not explained by variation in the skin temperature and vice versa. Therefore, a high  $R^2$  value is desirable. S-Plus software was used to predict the value of  $R^2$ .

### 24.6 Receiver Operating Curve (ROC) Analysis

The diagnostic performance of a test, or the ability of a test to discriminate diseased cases from normal cases is evaluated using ROC curve analysis (Shapiro, 1999; Ng, 2004; ROC, 2004). Perfect separation is rarely observed when we consider the result of a particular test in two populations, one population with a disease and the other without the disease. This is shown in Figure 24.8.

FIGURE 24.7 Linear regression line of body temperature vs. skin temperature (eye region). Data from ABCD set.

FIGURE 24.8 Test result.

It is common to define a threshold or decision limit  $\gamma$  and classify the patient as diseased if  $A > \gamma$  and normal if  $A < \gamma$  as illustrated in Figure 24.8. However, when defining a particular decision limit  $\gamma$  to discriminate between the two populations, some cases with the disease will be correctly classified as positive, True Positive (TP), but some cases with the disease will be classified as negative, False Negative (FN). On the other hand, some cases without the disease will be classified as positive, False Positive (FP), but some cases without the disease will be classified as negative, True Negative (TN). The following statistics can then be defined:

- *Sensitivity*: Probability that a test result will be positive when the disease is present (true positive rate, expressed as a percentage)
- *Specificity*: Probability that a test result will be negative when the disease is not present (true negative rate, expressed as a percentage)
- *Positive likelihood ratio*: Ratio between the probability of a positive test result given the presence of the disease and the probability of a positive test result given the absence of the disease
- *Negative likelihood ratio*: Ratio between the probability of a negative test result given the presence of the diseased and the probability of a negative test given the absence of the disease
- *Positive predictive value*: Probability that the disease is present when the test is positive (expressed as a percentage)
- *Negative predictive value*: Probability that the disease is not present when the test is negative (expressed as a percentage)
- *Accuracy*: The overall percentage of correct test results

Each decision limit  $\gamma$  gives a different set of results. Sensitivity and specificity can be used to estimate the decision limit. However, as  $\gamma$  decreases, sensitivity increases but specificity decreases and vice versa. It can be seen that there is a trade off between sensitivity and specificity as the decision limit varies. This implies that there must be an optimum decision limit  $\gamma$  with the highest accuracy, that is, the point with the best discrimination of the positive and negative cases. A useful graphical summary of discriminating accuracy is a plot of sensitivity vs.  $(1 - \text{specificity})$  as  $\gamma$  varies. This is known as the ROC curve. MedCalc (version 7.4) software (ROC, 2004) was used for ROC curve analysis and a dichotomous variable with quantitative result must be input. The dichotomous variable selected was that of body temperature and the quantitative result used was skin temperature. Figure 24.9 shows the ROC curve of the ABD data set and Table 24.3 is the associated ROC report.

The cross-point marked on the ROC curve is the point with highest accuracy. From the ROC report, the optimum cutoff was also identified as the criterion with a \* marked at its side. This value is  $> 34.6$  in Table 24.3. Therefore  $34.6^\circ\text{C}$  is the recommended skin temperature cutoff from the ROC analysis. The ROC area was used to determine the ability of the test to discriminate febrile from normal cases and the value can be read off from the ROC report. From Table 24.3, the ROC area is 0.907. This means that a randomly selected individual from the febrile group has a test value larger than that for a randomly chosen individual from a normal group in 90.7% of the time. When the variables under study cannot distinguish between the two groups, the area will be equal to 0.5 (the ROC curve will coincide with the diagonal). When there is a perfect separation of the values of the two groups, the ROC area will be equals 1 (the ROC curve will reach the upper left corner of the plot). A larger ROC area is desirable as it implies that there is a better separation of the two groups of patients.

## 24.7 Artificial Neural Networks (ANNs) Analysis

---

Next, neural networks (NN) based mapping and classification have been used to analyze the temperature data collected from various sites on the face on both the frontal and side profiles (Ng and Kaw, 2004). Two networks namely single layer perception (SLP) back propagation (BP) and Kohonen self-organizing map (SOM) are experimented with different learning rules, transfer parameter settings, and the number of hidden neurons in order to decide networks that appear to perform reasonably well on both the

FIGURE 24.9 ROC curve of skin temperature (eye range) at body cutoff of 37.7°C. Data from ABD set.

training and testing data. Each network performance is measured informally on the basis of the RMS level. The best-trained network setting is subsequently saved in binary mode with a suitable filename. The performance of those two networks is evaluated more formally using a scoring system with the threshold of 0.5. Based on the score results, the threshold value is determined and used consistently. Once the evaluation of the two networks is completed, a good performance network is then selected.

## 24.8 Results and Discussions

### 24.8.1 General Linear Regression Analysis

The linear regression analysis was performed using S-Plus (version 6.1) software for different combinations of data collected from TTSH and SCDF. The best-fitted curve of body and skin temperatures (eye range) was plotted and their results were tabulated in Table 24.4.

The intercept  $\alpha$  has no physical meaning and is of no actual interest in this chapter but is added in the result for completeness. The interest of regression analysis would be the regression ratio  $\beta$  and  $R^2$ . Comparing the original data sets A, B, C, and D, the regression ratio  $\beta$  is best for data set B: TTSH (2 days). The next best is data set D: TTSH (3 days) followed by those for data set A: TTSH (2 weeks). Data set C has the worse regression ratio. Similar trend had been observed for the value of  $R^2$  with the exception of data set D being the highest followed by data set B. It was found that data set C has an exceptionally low  $\beta$  and  $R^2$  values of 0.5133 and 0.1367. In other words, the body and skin temperatures (eye range) of data set C have very weak relationship. This is due to the fact that SCDF data has all nonfever (majority are young males with mean age of 23) data thereby making the sample bias. This observation was further proven by comparison made between data set AB, AC, and AD. Data set AC showed relatively low values for  $\beta$  and  $R^2$ . This was expected since data C already has low  $\beta$  and  $R^2$  values. Comparison between data set ABC and ABD also indicated similar results. When data set C was added to data set ABD, forming data set ABCD, the results showed lower  $\beta$  and  $R^2$  values as compared to those of data set ABD. This can be explained by the same reasoning.

On the contrary, data set BD has relatively high  $\beta$  and  $R^2$  coefficients. This was attributed by high  $\beta$  and  $R^2$  coefficients of the two individual sets of data. It thus suggested that data sets B and D possess a

good relationship of body temperature with skin temperature (eye region). However, these two data sets have too few data points for their analysis to be meaningful. Even the combination of the two sets of data was still inadequate as there were only 90 cases. Results from the data sets of different sample sizes would also be expected to differ and it would be unfair to compare them. Having a larger sample size, would make the analysis more accurate and representative. Due to bias present in data set C, it was only right to exclude it from further analysis. Data set ABD was thus potentially the more representative set with a sample size of 400. It should also be noted that the individual data of set ABD were all collected using the same scanner settings and this consistency is important for the combination of data. From Table 24.4, the

Recommended cutoff (°C)	35.5	36.1

$\beta$  and  $R^2$  value for data set ABD was 0.4369 and 0.5016 respectively. These were average values implying a reasonable relationship between body and skin temperatures (eye region), despite the presence of external variability such as environmental conditions, the patient's condition, and differing experience of operators obtaining the data.

## 24.8.2 General ROC Curve Analysis

ROC analysis has also been conducted for data set ABD and ABCD using MedCalc software. Skin temperatures measured from the eye region were used. The results using cutoff body temperature of 37.5, 37.7, 37.9, and 38.0°C are summarized in Table 24.5.

It can be seen from the results in Table 24.5 that sensitivity decreases and specificity increases as the cutoff decision limit,  $\gamma$ , increases. Similarly, increasing  $\gamma$  results in the false negative rate increasing and the false positive rate decreasing. Both the ROC areas of data set ABD and ABCD presented in Table 24.5 were high. This means that infrared thermography possesses great potential in differentiating subjects with elevated body temperature from normal cases during the blind mass screening of subjects. The accuracy

of the ROC analysis for both sets of data was also high. This reinforces the potential of using an infrared system for the identification of a person with an elevated body temperature. The values of false positive and false negative of both sets of data at different cutoff have also shown promise of infrared thermography for screening febrile cases accurately from normal cases. The false positive and false negative values of both data sets at different cutoff temperatures shows that febrile subjects can be differentiated accurately from normal ones. As indicated in Table 24.5, these values generally fall below 10%. A low false positive rate implies that the infrared system has erroneously classified few normal cases as febrile cases. Similarly a low false negative rate would mean that the scanner has erroneously classified few febrile cases as normal cases. The latter could be avoided with a lower cutoff temperature.

### 24.8.3 Statistical Analysis on Data Sets E and F

Regression analysis was also performed on the data set F. This was to determine the site on the face with the best correlation with the core body temperature. The results are tabulated in Table 24.6.

Table 24.6 shows that the averaged (ave) temple readings have the highest values for both the  $\beta$  and  $R^2$  coefficients.  $\beta$  and  $R^2$  values for the side temple and eye region were also close to those of the ave temples. This suggested that the skin temperature measured from temple region offered a relatively better relationship with the body temperature. The eye region also shows a good correlation as its coefficients differed only slightly from the ave temple and side temple readings. However, there were only 65 samples in this data set. This may not be proven statistically significant. Table 24.7 tabulated the linear regression of body and skin temperatures of various sites on the face taken from the frontal profile (data set E) only. The sample size in this set of data was 187, which was more representative and thus the ROC analysis was performed for this sample.

Referring to Table 24.7, eye region has the highest  $\beta$  and  $R^2$  values. Ave temples also have high  $\beta$  and  $R^2$  values. Based on the results from the regression analysis, the skin temperature measured from eye

**TABLE 24.6** Results of Regression Analysis Performed on Body and Skin Temperatures (Data Set F) Measured from Various Sites

Description	Regression ratio $\beta$	Intercept $\alpha$	$R^2$
Frontal			
Forehead	0.4206	22.5443	0.3495
Eye range	0.5175	19.2068	0.4005

region, has a good relationship with body temperature. A ROC analysis was performed for this data and the results are shown in Table 24.8.

From the ROC analysis, it was observed that sensitivity decreases and specificity increases as the cutoff decision limit,  $\gamma$ , increases. In other words, increasing  $\gamma$  leads to increasing of false negative rate and decreasing of false positive rate. The ROC areas for all the different sites at different cutoff temperatures were relatively high. This concludes that the current IR system can distinguish persons with elevated body temperature from normal subjects rather well from the skin temperatures measured at various sites as presented in Table 24.8. The ROC analysis showed that the skin temperatures of the ave temples resulted in a higher ROC area than those from eye region although the two sets of results were close. The only exception was observed at the cutoff of  $37.7^{\circ}\text{C}$  where the ROC area for eye region was higher than that of the ave temples. However, the results also suggested that the sensitivity and accuracy of the eye region for the entire cutoff temperature range were slightly higher. False negative rates were also lower for the eye region. False positive rates were low for both sets of data. It can be deduced from the regression and ROC analysis that the eye region has a slightly better overall performance for. Figure 24.10 shows that there are quite a few arteries around the eye. Thus, a small area of the skin near the eyes and nose offers the body temperature to be measured since the thin skin in this area has the highest amount of light energy thus making it a preferred point for brain temperature tunnel.

#### 24.8.4 General ANNs Analysis

In the SLP-BP-NN experiment, different parameters are tested at each time to choose the best parameter for multilayer perception (MLP) evaluation in order to achieve a good score with different numbers of hidden neurons. In Kohonen SOM network, the  $10 \times 10$  Kohonen layer has a better performance ( $>97.3\%$ ) to classify the classes. Increasing the number of hidden neurons will improve the performance but the score will descend if the number of hidden neurons is exceeded. Thus, from the NN results, it shows that such type of NN (Ng and Chong, 2004) can be used as clinical decision support system for mass screening of febrile subjects.

## 24.9 Conclusions

From the results of the biostatistical analysis, the use of thermal imagers for the detection of persons with elevated body temperature during mass blind screening is very promising. The biostatistical analysis performed on readings from the eye region shows generally high ROC area values. ROC analysis performed on readings taken from other sites also showed high ROC area values. Since ROC area was used to

determine how well infrared thermography could be applied to differentiate febrile from normal cases, it seemed that there was great potential in using this technology for deterring entry of SARS (with elevated body temperature) across the checkpoints.

Accurate detection of fever by thermal imager requires a body surface site that can correlate well for representation of body temperature physiologically. From the regression analysis, the best reading was taken from the eye range followed by the ave temples. The quick observation of the ROC results seemed that the readings taken from ave temples have higher ROC area. Further analysis showed that the accuracy and sensitivity of skin temperatures from eye range, however, has higher values than the ave temples for the entire cutoff. False negative rates of eye range are also lower than those of ave temples. Moreover, the human anatomy has suggested that the eye region has several arteries and potentially a good point for entry of the brain temperature tunnel too.

The aim of blind mass screening for SARS, is to have a speedy noninvasive and fairly accurate method of detecting people with elevated body temperature and at the same time minimize inconvenience and disruption to human traffic. Therefore, obtaining temperature readings from a site on the face would be

most practical. The temples site for measuring skin surface of a person with fever is frequently met with the problem of the area being covered by hair or even accessories such as caps, hats, turban, and even tudung. Eye range provides a comparatively more practical site for this application.

The ROC analysis revealed that the thermal imager cutoff should be set to 34.6°C to detect aural temperatures of 37.5°C and above with respect to the associated environment. Similar cutoff of temperature for the thermal imagers has been found for detecting aural temperature above 37.7°C and 37.9°C. For detecting aural temperature of 38.0°C and above, the cutoff for thermal imager would have to be set at 35.5°C. Any temperature readings that exceed the thermal imager's cutoff would trigger the alarm and a thermometer would be used to verify the actual fever status of the subject.

The results of the ANN analysis further confirm that the use of thermal imagers for the detection of persons with elevated body temperature during mass blind screening is a very promising tool. Both BP and SOM can form an opinion about the type of network that is better to complement thermogram technology in fever diagnosis to drive better parameters for reducing the size of the neural network classifier while maintaining good classification accuracy. We observe that BP performs better than SOM neural network.

In order to ensure accurate collection of data, specific test procedures, and the physical requirements of the test sites will need to be standardized (Spring, 2003, 2004). Improper use of IR equipment, improper preparation of subjects, and improper collection of data can cause erroneous readings resulting in both false negative and false positive diagnosis. In summary, though IR thermography is promising for mass screening of potential SARS carriers, the technology must be applied with caution. Misapplication of the technology will not only waste resources, but can endanger the public safety by allowing infected persons to slip past and further spread the disease. The IR thermography applied for mass screening should therefore be used to complement and not replace the conventional thermometers (i.e., 2nd defense).

## Acknowledgments

The first author would like to express utmost appreciation to research associates, Mr. Chang W.M. and Miss Ong C.F. for their efforts and hard works in collecting the data from the hospital and SCDF. He also want to express his thanks to members of the Ad-hoc Technical Reference Committee on Thermal Imagers under Medical Technology Standards Division by SPRING, and Ministry of Health, TTSH of National Health Group, Singapore for sharing of their views and interests on "Thermal Imagers for Fever Screening — Selection, Usage, and Testing." Gratitude is also extended to the people who have helped the authors to accomplish the project in one-way or another.

### Prologue

The use of infrared imaging in health care is not a recent phenomenon. Its utilization in breast cancer screening, however, is seeing renewed interest. This attention is fueled by research that clearly demonstrates the value of this procedure and the tremendous impact it has on the mortality of breast cancer.

Infrared imaging of the breast has undergone extensive research since the late 1950s. Over 800 papers can be found in the indexed medical literature. In this database, well over 300,000 women have been included as study participants. The number of participants in many studies are very large and range from 10,000 to 85,000 women. Some of these studies have followed patients up to 12 years in order to establish the technology's ability as a risk marker.

With strict standardized interpretation protocols having been established for over 15 years, infrared imaging of the breast has obtained an average sensitivity and specificity of 90%. As a future risk indicator for breast cancer, a persistent abnormal thermogram carries a 22 times higher risk and is 10 times more

significant than a first order family history of the disease. Studies clearly show that an abnormal infrared image is the single most important risk marker for the existence of or future development of breast cancer.

## 25.1 Introduction

---

The first recorded use of thermobiological diagnostics can be found in the writings of Hippocrates around 480 BC [1]. A mud slurry spread over the patient was observed for areas that would dry first and was thought to indicate underlying organ pathology. Since this time, continued research and clinical observations proved that certain temperatures related to the human body were indeed indicative of normal and abnormal physiologic processes.

In the 1950s, military research into infrared monitoring systems for nighttime troop movements ushered in a new era in thermal diagnostics. Once declassified in the mid-1950s, infrared imaging technology was made available for medical purposes. The first diagnostic use of infrared imaging came in 1956 when Lawson discovered that the skin temperature over a cancer in the breast was higher than that of normal tissue [2–4]. He also showed that the venous blood draining the cancer is often warmer than its arterial supply.

The Department of Health Education and Welfare released a position paper in 1972 in which the director, Thomas Tierney, wrote, “The medical consultants indicate that thermography, in its present state of development, is beyond the experimental state as a diagnostic procedure in the following 4 areas: (1) Pathology of the female breast. . .” On January 29, 1982, the Food and Drug Administration published its approval and classification of thermography as an adjunctive diagnostic screening procedure for the detection of breast cancer. Since the late 1970s, numerous medical centers and independent clinics have used thermography for a variety of diagnostic purposes.

Since Lawson’s groundbreaking research, infrared imaging has been used for over 40 years as an adjunctive screening procedure in the evaluation of the breast. In this time significant advances have been made in infrared detection systems and the application of sophisticated computerized image processing.

## 25.2 Fundamentals of Infrared Breast Imaging

---

Clinical infrared imaging is a procedure that detects, records, and produces an image of a patient’s skin surface temperatures and thermal patterns. The image produced resembles the likeness of the anatomic area under study. The procedure uses equipment that can provide both qualitative and quantitative representations of these temperature patterns.

Infrared imaging does not entail the use of ionizing radiation, venous access, or other invasive procedures; therefore, the examination poses no harm to the patient. Classified as a functional imaging technology, infrared imaging of the breast provides information on the normal and abnormal physiologic functioning of the sensory and sympathetic nervous systems, vascular system, and local inflammatory processes.

### 25.2.1 Physics

All objects with a temperature above absolute zero ( $-273$  K) emit infrared radiation from their surface. The Stefan-Boltzmann Law defines the relation between radiated energy and temperature by stating that the total radiation emitted by an object is directly proportional to the object’s area and emissivity and the fourth power of its absolute temperature. Since the emissivity of human skin is extremely high (within 1% of that of a black body), measurements of infrared radiation emitted by the skin can be converted directly into accurate temperature values. This makes infrared imaging an ideal procedure to evaluate surface temperatures of the body.

### 25.2.2 Equipment Considerations

Infrared rays are found in the electromagnetic spectrum within the wavelengths of 0.75  $\mu\text{m}$  to 1 mm. Human skin emits infrared radiation mainly in the 2–20  $\mu\text{m}$  wavelength range, with an average peak at 9–10  $\mu\text{m}$  [5]. With the application of Planck's equation and Wein's Law, it is found that approximately 90% of emitted infrared radiation in humans is in the longer wavelengths (6–14  $\mu\text{m}$ ).

There are many important technical aspects to consider when choosing an appropriate clinical infrared imaging system (the majority of which is outside the scope of this chapter). However, minimum equipment standards have been established from research studies, applied infrared physics, and human anatomic and physiologic parameters [6,7]. Absolute, spatial, and temperature resolution along with thermal stability and adequate computerized image processing are just a few of the critical specifications to take into account. However, the most fundamental consideration in the selection of clinical infrared imaging equipment is the wavelength sensitivity of the infrared detector. The decision on which area in the infrared spectrum to select a detector from depends on the object one wants to investigate and the environmental conditions in which the detection is taking place. Considering that the object in question is the human body, Planck's equation leads us to select a detector in the 6–14  $\mu\text{m}$  region. Assessment of skin temperature by infrared measurement in the 3–5  $\mu\text{m}$  region is less reliable due to the emissivity of human skin being farther from that of a blackbody in that region [8,9]. The environment under which the examination takes place is well controlled, but not free from possible sources of detection errors. Imaging room environmental artifacts such as reflectance can cause errors when shorter wavelength detectors (under 7  $\mu\text{m}$ ) are used [10]. Consequently, the optimum infrared detector to use in imaging the breast, and the body as a whole, would have a sensitivity in the longer wavelengths spanning the 9–10  $\mu\text{m}$  range [7–14].

The problems encountered with first generation infrared camera systems, such as incorrect detector sensitivity (shorter wavelengths), thermal drift, calibration, analog interface, and so on, have been solved for almost two decades. Modern computerized infrared imaging systems have the ability to discern minute variations in thermal emissions while producing extremely high-resolution images that can undergo digital manipulation by sophisticated computerized analytical processing.

### 25.2.3 Laboratory and Patient Preparation Protocols

In order to produce diagnostic quality infrared images, certain laboratory and patient preparation protocols must be strictly adhered to. Infrared imaging must be performed in a controlled environment. The primary reason for this is the nature of human physiology. Changes from a different external (noncontrolled room) environment, clothing, and the like, produce thermal artifacts. In order to properly prepare the patient for imaging, the patient should be instructed to refrain from sun exposure, stimulation or treatment of the breasts, cosmetics, lotions, antiperspirants, deodorants, exercise, and bathing before the exam.

The imaging room must be temperature and humidity-controlled and maintained between 18 and 23°C, and kept to within 1°C of change during the examination. This temperature range insures that the patient is not placed in an environment in which their physiology is stressed into a state of shivering or perspiring. The room should also be free from drafts and infrared sources of heat (i.e., sunlight and incandescent lighting). In keeping with a physiologically neutral temperature environment, the floor should be carpeted or the patient must wear shoes in order to prevent increased physiologic stress.

Lastly, the patient must undergo 15 min of waist-up nude acclimation in order to reach a condition in which the body is at thermal equilibrium with the environment. At this point, further changes in the surface temperatures of the body occur very slowly and uniformly; thus, not affecting changes in homologous anatomic regions. Thermal artifacts from clothing or the outside environment are also removed at this time. The last 5 min of this acclimation period is usually spent with the patient placing their hands on top of their head in order to facilitate an improved anatomic presentation of the breasts for imaging. Depending

FIGURE 25.1 (See color insert following page 29-16.) Bilateral frontal.

FIGURE 25.2 (See color insert.) Right oblique.

on the patient's individual anatomy, certain positioning maneuvers may need to be implemented such that all of the pertinent surfaces of the breasts may be imaged. In summary, adherence to proper patient and laboratory protocols is absolutely necessary to produce a physiologically neutral image, free from artifact and ready for interpretation.

### 25.2.4 Imaging

The actual process of imaging is undertaken with the intent to adequately detect the infrared emissions from the pertinent surface areas of the breasts. As with mammography, a minimum series of images is needed in order to facilitate adequate coverage. The series includes the bilateral frontal breast along with the right and left oblique views (a right and left single breast close-up view may also be included). The bilateral frontal view acts as a scout image to give a baseline impression of both breasts. The oblique views (approximately 45° to the detector) expose the lateral and medial quadrants of the breasts for analysis. The optional close-up views maximize the use of the detector allowing for the highest thermal and spatial resolution image of each breast. This series of images takes into consideration the infrared analyses of curved surfaces and adequately provides for an accurate analysis of all the pertinent surface areas of the breasts (see Figure 25.1 to Figure 25.5).

Positioning of the patient prior to imaging facilitates acclimation of the surface areas and ease of imaging. Placing the patient in a seated or standing posture during the acclimation period is ideal to facilitate these needs. In the seated position, the patient places their arms on the arm rests away from the body to allow for proper acclimation. When positioning the patient in front of the camera, the use of a rotating chair or having the patient stand makes for uncomplicated positioning for the necessary views.

Because of differing anatomy from patient to patient, special views may be necessary to adequately detect the infrared emissions from the pertinent surface areas of the breasts. The most common problem

FIGURE 25.3 (See color insert.) Left oblique.

FIGURE 25.4 (See color insert.) Right close-up.

FIGURE 25.5 (See color insert.) Left close-up.

encountered is inadequate viewing of the inferior quadrants due to nipple ptosis. This is easily remedied by adding “lift views.” Once the baseline images are taken, the patient is asked to “lift” each breast from the Tail of Spence exposing the inferior quadrants for detection. Additional images are then taken in this position in order to maintain the surface areas covered in the standard views.

### 25.2.5 Special Tests

In the past, an optional set of views may have been added to the baseline images. Additional views would be taken after the patient placed their hands in ice cold water as a thermoregulatory cold challenge. It was hoped that this dynamic methodology would increase the sensitivity and specificity of the thermographic procedure.

In order to understand the hopes placed on this test, one needs to understand the underlying physiologic mechanisms of the procedure. The most common and accepted method of applied thermoregulatory challenge involves ice water immersion of the hands or feet (previous studies investigating the use of fans or alcohol spray noted concerns over the creation of thermal artifacts along with the methods causing a limited superficial effect). The mechanism is purely neurovascular and involves a primitive survival reflex initiated from peripheral neural receptors and conveyed to the central nervous system. To protect the body from hypothermia, the reflex invokes a sympathetically mediated blood vessel constriction in the periphery in an attempt to maintain the normal core temperature set point. This stress test is intended to increase the sensitivity of the thermogram by attempting to identify nonresponding blood vessels such as those involved in angiogenesis associated with neoplasm. Blood vessels produced by cancerous tumors are simple endothelial tubes devoid of a muscular layer and the neural regulation afforded to embryologic vessels. As such, these new vessels would fail to constrict in response to a sympathetic stimulus. In the normal breast, test results would produce an image of relative cooling with attenuation of vascular diameter. A breast harboring a malignancy would theoretically remain unchanged in temperature or demonstrate hyperthermia with vascular dilation. However, to date it has not been found that the stress test offers any advantage over the baseline images [15].

For well over a decade, leading experts and researchers in the field of infrared breast imaging have discontinued the use of the cold challenge. Yet, in a 2004 detailed review of the literature combined with an investigational study, Amalu [15] explored the validity of the cold challenge test. Results from 23 patients with histologically confirmed breast cancers along with 500 noncancer cases were presented demonstrating positive and negative responses to the challenge. From the combined literature review and study analysis it was found that the test did not alter the clinical decision-making process for following up suspicious thermograms, nor did it enhance the detection of occult cancers found in normal thermograms. In summary, it was found that there was no evidence to support the use of the cold challenge. The study noted insufficient evidence to warrant its use as a mandated test with all women undergoing infrared breast imaging. It also warned that it would be incorrect to consider a breast thermogram “substandard” if a cold challenge was not included. In conclusion, Amalu stated that “Until further studies are performed and ample evidence can be presented to the contrary, a review of the available data indicates that infrared imaging of the breast can be performed excluding the cold challenge without any known loss of sensitivity or specificity in the detection of breast cancers.”

### 25.2.6 Image Interpretation

Early methods of interpretation of infrared breast images was based solely on qualitative (subjective) criteria. The images were read for variations in vascular patterning with no regard to temperature variations between the breasts (Tricore method) [16]. This led to wide variations in the outcomes of studies performed with inexperienced interpreters. Research throughout the 1970s proved that when both qualitative and quantitative data were incorporated in the interpretations, an increase in sensitivity and specificity was realized. In the early 1980s, a standardized method of thermovascular analysis was proposed. The interpretation was composed of 20 discrete vascular and temperature attributes in the breast [17,18]. This method of analysis was based on previous research and large scale studies comprising tens of thousands of patients. Using this methodology, thermograms would be graded into 1 of 5 TH (thermobiological) classifications. Based on the combined vascular patterning and temperatures across the two breasts, the images would be graded as TH1 (normal nonvascular), TH2 (normal vascular), TH3 (equivocal), TH4 (abnormal), or TH5 (severely abnormal) (see Figure 25.6 and Figure 25.7). The use of this standardized interpretation method significantly increased infrared imaging’s sensitivity, specificity, positive and negative predictive value, and inter/intra-examiner interpretation reliability. Continued patient observations and research over the past two decades have caused changes in some of the thermovascular values; thus, keeping the interpretation system up-to-date. Variations in this methodology have also been adopted with great success. However, it is recognized that, as with any other imaging procedure, specialized training and experience produces the highest level of screening success.

FIGURE 25.7 (See color insert.) Left TH5 (severely abnormal).

## 25.3 Correlation between Pathology and Infrared Imaging

The empirical evidence that an underlying breast cancer alters regional skin surface temperatures was investigated early on. In 1963, Lawson and Chughtai, two McGill University surgeons, published an elegant intra-operative study demonstrating that the increase in regional skin surface temperature associated with breast cancer was related to venous convection [19]. This early quantitative experiment added credence to previous research suggesting that infrared findings were linked to increased vascularity.

Infrared imaging of the breast may also have critical prognostic significance since it may correlate with a variety of pathologic prognostic features such as tumor size, tumor grade, lymph node status, and markers of tumor growth [20]. Continued research is underway investigating the pathologic basis for these infrared findings. One possibility is increased blood flow due to vascular proliferation (assessed by quantifying the microvascular density [MVD]) as a result of tumor associated angiogenesis. Although in one study [21], the MVD did not correlate with abnormal infrared findings. However, the imaging method used in that study consisted of contact plate technology (liquid crystal thermography [LCT]), which is not capable of modern computerized analysis. Consequently, LCT does not possess the discrimination and digital processing necessary to begin to correlate histological and discrete vascular changes [22].

In 1993, Head and Elliott reported that improved images from second generation infrared systems allowed more objective and quantitative analysis [20], and indicated that growth-rate related prognostic indicators were strongly associated with the infrared image interpretation.

In a 1994 detailed review of the potential of infrared imaging [23], Anbar suggested that the previous empirical observation that small tumors were capable of producing notable infrared changes could be due to enhanced perfusion over a substantial area of the breast surface via regional tumor induced nitric oxide (NO) vasodilatation. NO is synthesized by nitric oxide synthase (NOS), found both as a constitutive form of NOS, especially in endothelial cells, and as an inducible form of NOS, especially in macrophages

[24]. NOS has been demonstrated in breast carcinoma [25] using tissue immunohistochemistry, and is associated with a high tumor grade.

Nitric oxide is a molecule with potent vasodilating properties. It is a simple highly reactive free radical that readily oxidizes to form nitrite or nitrate ions. It diffuses easily through both hydrophilic and hydrophobic media. Thus, once produced, NO diffuses throughout the surrounding tissues, inside and outside the vascular system, and induces a variety of biochemical changes depending on the specific receptors involved. NO exerts its influence by binding to receptor sites in the endothelium of arteries or arterioles. This causes inhibition of sympathetic vasoconstriction. The end result is NO induced vasodilatation, which in turn may produce an asymmetrical thermovascular infrared image.

The largest body of evidence surrounding the physiologic mechanism by which infrared imaging detects precancerous and malignant states of the breast lies in the recruitment of existing blood vessels and the formation of new ones (angiogenesis). The process of angiogenesis begins with the release of angiogenesis factors (AF) from precancerous or cancerous cells. In the early stages of tumor growth, the majority of neoplasms exhibit a lower cellular metabolic demand. As such, the release of AF causes the existing vessels to resist constriction in order to maintain a steady supply of nutrients to the growing mass. As the tumor increases in size the need for nutrients becomes greater. AF begins to exert its influence by opening the dormant vessels in the breast. Once this blood supply becomes too little to maintain the growth of the neoplasm, AF causes the formation of new blood vessels. These new vessels are simple endothelial tubes connecting the tumor to existing nearby arteries and arterioles. This augmented blood supply produces the increase in heat and vascular asymmetry seen in infrared images.

The concept of angiogenesis, as an integral part of early breast cancer, was emphasized in 1996 by Guido and Schnitt. Their observations suggested that it is an early event in the development of breast cancer and may occur before tumor cells acquire the ability to invade the surrounding stroma and even before there is morphologic evidence of an *in situ* carcinoma [26]. In 1996, in his highly reviewed textbook entitled *Atlas of Mammography — New Early Signs in Breast Cancer*, Gamagami studied angiogenesis by infrared imaging and reported that hypervascularity and hyperthermia could be shown in 86% of nonpalpable breast cancers. He also noted that in 15% of these cases infrared imaging helped to detect cancers that were not visible on mammography [27].

The greatest evidence supporting the underlying principle by which infrared imaging detects precancerous growths and cancerous tumors surrounds the well documented recruitment of existing vascularity and angiogenesis, which is necessary to maintain the increased metabolism of malignant cellular growth and multiplication. The biomedical engineering evidence of infrared imaging's value, both in model *in vitro* and clinically *in vivo* studies of various tissue growths, normal and neoplastic, has been established [28–34].

## 25.4 The Role of Infrared Imaging in the Detection of Cancer

---

In order to determine the value of infrared imaging, two viewpoints must be considered: first, the sensitivity of thermograms taken preoperatively in patients with known breast carcinoma; and second, the incidence of normal and abnormal thermograms in asymptomatic populations (specificity) and the presence or absence of malignancy in each of these groups.

In 1965, Gershon-Cohen et al. [35], a radiologist and researcher from the Albert Einstein Medical Center, introduced infrared imaging to the United States [35]. Using a Barnes thermograph, he reported on 4000 cases with a sensitivity of 94% and a false-positive rate of 6%. This data was included in a review of the then current status of infrared imaging published in 1968 in *CA — A Cancer Journal for Physicians* [36].

In prospective studies, Hoffman first reported on thermography in a gynecologic practice. He detected 23 carcinomas in 1924 patients (a detection rate of 12.5 per 1000), with an 8.4% false-negative (91.6% sensitivity) and a 7.4% false-positive (92.6% specificity) rate [37].

Stark and Way [38] screened 4621 asymptomatic women, 35% of whom were under 35 years of age, and detected 24 cancers (detection rate of 7.6 per 1000), with a sensitivity and specificity of 98.3 and 93.5%, respectively.

In a study comprising 25,000 patients screened and 1,878 histologically proven breast cancers, Amalric and Spitalier reported on their results with infrared imaging. From this group a false-negative and false-positive rate of 9% (91% sensitivity and specificity) was found [39].

In a mobile unit examination of rural Wisconsin, Hobbins screened 37,506 women using thermography. He reported the detection of 5.7 cancers per 1,000 women screened with a 12% false-negative and 14% false-positive rate. His findings also corroborated with others that thermography is the sole early initial signal in 10% of breast cancers [17,40].

Reporting his Radiology division's experience with 10,000 thermographic studies done concomitantly with mammography over a 3-year period, Isard reiterated a number of important concepts including the remarkable thermal and vascular stability of the infrared image from year to year in the otherwise healthy patient and the importance of recognizing any significant change [41]. In his experience, combining these modalities increased the sensitivity rate of detection by approximately 10%; thus, underlining the complementarity of these procedures since each one did not always suspect the same lesion. It was Isard's conclusion that, had there been a preliminary selection of his group of 4393 asymptomatic patients by infrared imaging, mammographic examination would have been restricted to the 1028 patients with abnormal infrared imaging, or 23% of this cohort. This would have resulted in a cancer detection rate of 24.1 per 1000 combined infrared and mammographic examinations as contrasted to the expected 7 per 1000 by mammographic screening alone. He concluded that since infrared imaging is an innocuous examination, it could be utilized to focus attention upon asymptomatic women who should be examined more intensely. Isard emphasized that, like mammography and other breast imaging techniques, infrared imaging does not diagnose cancer, but merely indicates the presence of an abnormality.

Spitalier and associates screened 61,000 women using thermography over a 10-year period. The false-negative and positive rate was found to be 11% (89% sensitivity and specificity). Thermography also detected 91% of the nonpalpable cancers (Grade T0: tumors less than 1 cm in size). The authors noted that of all the patients with cancer, thermography alone was the first alarm in 60% of the cases [42].

Two small-scale studies by Moskowitz (150 patients) [43] and Treatt (515 patients) [44] reported on the sensitivity and reliability of infrared imaging. Both used unknown experts to review the images of breast cancer patients. While Moskowitz excluded unreadable images, data from Threatt's study indicated that less than 30% of the images produced were considered good, the rest being substandard. Both of these studies produced poor results; however, this could be expected considering the lack of adherence to accepted imaging methods and protocols. The greatest error in these studies is found in the methods used to analyze the images. The type of image analysis consisted of the sole use of abnormal vascular pattern recognition. At the time these studies were performed, the accepted method of infrared image interpretation consisted of a combined vascular pattern and quantitative analysis of temperature variations across the breasts. Consequently, the data obtained from these studies is highly questionable. Their findings were also inconsistent with numerous previous large-scale multicenter trials. The authors suggested that for infrared imaging to be truly effective as a screening tool, there needed to be a more objective means of interpretation and proposed that this would be facilitated by computerized evaluation. This statement is interesting considering that recognized quantitative and qualitative reading protocols (including computer analysis) were being used at the time.

In a unique study comprising 39,802 women screened over a 3-year period, Haberman and associates used thermography and physical examination to determine if mammography was recommended. They reported an 85% sensitivity and 70% specificity for thermography. Haberman cautioned that the findings of thermographic specificity could not be extrapolated from this study as it was well documented that long-term observation (8 to 10 years or more) is necessary to determine a true false-positive rate. The authors noted that 30% of the cancers found would not have been detected if it were not for thermography [45].

Gros and Gautherie reported on a large scale study comprising 85,000 patients screened. Culmination of the data resulted in a 90% sensitivity and 88% specificity for thermography [46–49].

In a large-scale multicenter review of nearly 70,000 women screened, Jones reported a false-negative and false-positive rate of 13% (87% sensitivity) and 15% (85% sensitivity) respectively for thermography [50].

In a study performed in 1986, Usuki reported on the relation of thermographic findings in breast cancer diagnosis. He noted an 88% sensitivity for thermography in the detection of breast cancers [51].

Parisky and associates published a study from a multicenter 4-year clinical trial using infrared imaging to evaluate mammographically suspicious lesions. Data from a blinded subject set was obtained in 769 women with 875 biopsied lesions resulting in 187 malignant and 688 benign findings. The index of suspicion resulted in a 97% sensitivity in the detection of breast cancers [52].

In a study comparing clinical examination, mammography, and thermography in the diagnosis of breast cancer, three groups of patients were used: 4,716 patients with confirmed carcinoma, 3,305 patients with histologically diagnosed benign breast disease, and 8,757 general patients (16,778 total participants). This paper also compared clinical examination and mammography to other well-known studies in the literature including the National Cancer Institute (NCI)-sponsored Breast Cancer Detection and Demonstration Projects. In this study, clinical examination had an average sensitivity of 75% in detecting all tumors and 50% in cancers less than 2 cm in size. This rate is exceptionally good when compared to many other studies at between 35 and 66% sensitivity. Mammography was found to have an average 80% sensitivity and 73% specificity. Thermography had an average sensitivity of 88% (85% in tumors less than 1 cm in size) and a specificity of 85%. An abnormal thermogram was found to have a 94% predictive value. From the findings in this study, the authors suggested that “none of the techniques available for screening for breast carcinoma and evaluating patients with breast related symptoms is sufficiently accurate to be used alone. For the best results, a multimodal approach should be used” [53].

In a series of 4,000 confirmed breast cancers, Thomassin and associates observed 130 subclinical carcinomas ranging in diameter of 3 to 5 mm. Both mammography and thermography were used alone and in combination. Of the 130 cancers, 10% were detected by mammography only, 50% by thermography alone, and 40% by both techniques. Thus, there was a thermal alarm in 90% of the patients and the only sign in 50% of the cases [54].

In a simple review of over 15 large-scale studies from 1967 to 1998, infrared imaging of the breast has showed an average sensitivity and specificity of 90%. With continued technological advances in infrared imaging in the past decade, some studies are showing even higher sensitivity and specificity values. However, until further large-scale studies are performed, these findings remain in question.

## 25.5 Infrared Imaging as a Risk Indicator

---

As early as 1976, at the Third International Symposium on Detection and Prevention of Cancer held in New York, thermal imaging was established by consensus as the highest risk marker for the possibility of the presence of an undetected breast cancer. It had also been shown to predict such a subsequent occurrence [55–57]. The Wisconsin Breast Cancer Detection Foundation presented a summary of its findings in this area, which has remained undisputed [58]. This, combined with other reports, has confirmed that an abnormal infrared image is the highest risk indicator for the future development of breast cancer and is 10 times as significant as a first order family history of the disease [48].

In a study of 10,000 women screened, Gautherie found that, when applied to asymptomatic women, thermography was very useful in assessing the risk of cancer by dividing patients into low and high risk categories. This was based on an objective evaluation of each patient’s thermograms using an improved reading protocol that incorporated 20 thermopathological factors [59].

A screening of 61,000 women using thermography was performed by Spitalier over a 10-year period. The authors concluded that “in patients having no clinical or radiographic suspicion of malignancy, a persistently abnormal breast thermogram represents the highest known risk factor for the future development of breast cancer” [42].

From a patient base of 58,000 women screened with thermography, Gros and associates followed 1527 patients with initially healthy breasts and abnormal thermograms for 12 years. Of this group, 44%

developed malignancies within 5 years. The study concluded that “an abnormal thermogram is the single most important marker of high risk for the future development of breast cancer” [49].

Spitalier and associates followed 1416 patients with isolated abnormal breast thermograms. It was found that a persistently abnormal thermogram, as an isolated phenomenon, is associated with an actuarial breast cancer risk of 26% at 5 years. Within this study, 165 patients with nonpalpable cancers were observed. In 53% of these patients, thermography was the only test which was positive at the time of initial evaluation. It was concluded that (1) A persistently abnormal thermogram, even in the absence of any other sign of malignancy, is associated with a high risk of developing cancer, (2) This isolated abnormal also carries with it a high risk of developing interval cancer, and as such the patient should be examined more frequently than the customary 12 months, (3) Most patients diagnosed as having minimal breast cancer have abnormal thermograms as the first warning sign [60,61].

In a study by Gautherie and associates, the effectiveness of thermography in terms of survival benefit was discussed. The authors analyzed the survival rates of 106 patients in whom the diagnosis of breast cancer was established as a result of the follow-up of thermographic abnormalities found on the initial examination when the breasts were apparently healthy (negative physical and mammographic findings). The control group consisted of 372 breast cancer patients. The patients in both groups were subjected to identical treatment and followed for 5 years. A 61% increase in survival was noted in the patients who were followed-up due to initial thermographic abnormalities. The authors summarized the study by stating that “the findings clearly establish that the early identification of women at high risk of breast cancer based on the objective thermal assessment of breast health results in a dramatic survival benefit” [62,63].

Infrared imaging provides a reflection of functional tumor induced angiogenesis and metabolic activity rather than structurally based parameters (i.e., tumor size, architectural distortion, microcalcifications). Recent advances in cancer research have determined that the biological activity of a neoplasm is far more significant an indicator of aggressiveness than the size of the tumor. As a direct reflection of the biological activity in the breast, infrared imaging has been found to provide a significant biological risk marker for cancer.

## 25.6 Infrared Imaging as a Prognostic Indicator

---

Studies exploring the biology of cancers have shown that the amount of thermovascular activity in the breast is directly proportional to the aggressiveness of the tumor. As such, infrared imaging provides the clinician with an invaluable tool in prognosis and treatment monitoring.

In a study of 209 breast cancers, Dilhuydy and associates found a positive correlation between the degree of infrared abnormalities and the existence of positive axillary lymph nodes. It was reported that the amount of thermovascular activity seen in the breast was directly related to the prognosis. The study concluded that infrared imaging provides a highly significant factor in prognosis and that it should be included in the pretherapeutic assessment of a breast cancer [64].

Amalric and Spitalier reported on 25,000 patients screened and 1,878 histologically proven breast cancers investigated with infrared imaging. The study noted that the amount of infrared activity in the breast was directly proportional to the survival of the patient. The “hot” cancers showed a significantly poorer prognosis with a 24% survival rate at 3 years. A much better prognosis with an 80% survival rate at 3 years was seen in the more biologically inactive or “cooler” cancers. The study also noted a positive association between the amount of thermal activity in the breast and the presence of positive axillary nodes [65].

Reporting on a study of breast cancer doubling times and infrared imaging, Fournier noted significant changes in the thermovascular appearance of the images. The shorter the tumor doubling time, the more thermographic pathological signs were evident. It was concluded that infrared imaging served as a warning signal for the faster-growing breast cancers [66].

A retrospective analysis of 100 normal patients, 100 living cancer patients, and 126 deceased cancer patients was published by Head. Infrared imaging was found to be abnormal in 28% of the normal patients, compared to 65% of the living cancer patients and 88% of the deceased cancer patients. Known

prognostic indicators related to tumor growth rate were compared to the results of the infrared images. The concentration of tumor ferritin, the proportion of cells in DNA synthesis and proliferating, and the expression of the proliferation-associated tumor antigen Ki-67 were all found to be associated with an abnormal infrared image. It was concluded that “The strong relationships of thermographic results with these three growth rate-related prognostic indicators suggest that breast cancer patients with abnormal thermograms have faster-growing tumors that are more likely to have metastasized and to recur with a shorter disease-free interval” [20].

In a paper by Gros and Gautherie, the use of infrared imaging in the prognosis of treated breast cancers was investigated. The authors considered infrared imaging to be absolutely necessary for assessing pretherapeutic prognosis or carrying out the follow-up of breast cancers treated by exclusive radiotherapy. They noted that before treatment, infrared imaging yields evidence of the cancer growth rate (aggressiveness) and contributes to the therapeutic choice. It also indicates the success of radiosterilization or the suspicion of a possible recurrence or radio-resistance. The authors also noted a weaker 5-year survival with infrared images that showed an increase in thermal signals [67].

In a recent study by Keyserlingk, 20 women with core biopsy-proven locally advanced breast cancer underwent infrared imaging before and after chemohormonotherapy. All 20 patients were found to have abnormal thermovascular signs prior to treatment. Upon completion of the final round of chemotherapy, each patient underwent curative-intent surgery. Prior to surgery, all 20 patients showed improvement in their initial infrared scores. The amount of improvement in the infrared images was found to be directly related to the decrease in tumor size. A complete normalization of prechemotherapy infrared scores was seen in five patients. In these same patients there was no histological evidence of cancer remaining in the breast. In summary, the authors stated that “Further research will determine whether lingering infrared detected angiogenesis following treatment reflects tumor aggressiveness and ultimately prognosis, as well as early tumor resistance, thus providing an additional early signal for the need of a therapeutic adjustment” [68].

## 25.7 Breast Cancer Detection and Demonstration Project

---

The breast cancer detection and demonstration project (BCDDP) is the most frequently quoted reason for the decreased interest in infrared imaging. The BCDDP was a large-scale study performed from 1973 through 1979, which collected data from many centers around the United States. Three methods of breast cancer detection were studied: physical examination, mammography, and infrared imaging.

Just before the onset of the BCDDP, two important papers appeared in the literature. In 1972, Gerald D. Dodd of the University of Texas Department of Diagnostic Radiology presented an update on infrared imaging in breast cancer diagnosis at the 7th National Cancer Conference sponsored by the National Cancer Society and the National Cancer Institute [69]. In his presentation, he suggested that infrared imaging would be best employed as a screening agent for mammography. He proposed that in any general survey of the female population aged 40 and over, 15 to 20% of these subjects would have positive infrared imaging and would require mammograms. Of these, approximately 5% would be recommended for biopsy. He concluded that infrared imaging would serve to eliminate 80 to 85% of the potential mammograms. Dodd also reiterated that the procedure was not competitive with mammography and, reporting the Texas Medical School’s experience with infrared imaging, noted that it was capable of detecting approximately 85% of all breast cancers. Dodd’s ideas would later help to fuel the premise and attitudes incorporated into the BCDDP.

Three years later, J.D. Wallace presented to another Cancer Conference, sponsored by the American College of Radiology, the American Cancer Society, and the Cancer Control Program of the National Cancer Institute, an update on infrared imaging of the breast [70]. The author’s analysis suggested that the incidence of breast cancer detection per 1000 patients screened could increase from 2.72 when using mammography to 19 when using infrared imaging. He then underlined that infrared imaging poses no radiation burden on the patient, requires no physical contact and, being an innocuous technique, could concentrate

the sought population by a significant factor selecting those patients who required further investigation. He concluded that, “the resulting infrared image contains only a small amount of information as compared to the mammogram, so that the reading of the infrared image is a substantially simpler task.”

Unfortunately, this rather simplistic and cavalier attitude toward the generation and interpretation of infrared images was prevalent when it was hastily added and then prematurely dismissed from the BCDDP, which was just getting underway. Exaggerated expectations led to the ill-founded premise that infrared imaging might replace mammography rather than complement it. A detailed review of the Report of the Working Group of the BCDDP, published in 1979, is essential to understand the subsequent evolution of infrared imaging [71].

The work scope of this project was issued by the NCI on the 26th of March 1973 with six objectives, the second being to determine if a negative infrared image was sufficient to preclude the use of clinical examination and mammography in the detection of breast cancer. The Working Group, reporting on results of the first 4 years of this project, gave a short history regarding infrared imaging in breast cancer detection. They wrote that, as of the sixties, there was intense interest in determining the suitability of infrared imaging for large-scale applications, and mass screening was one possibility. The need for technological improvement was recognized and the authors stated that efforts had been made to refine the technique. One of the important objectives behind these efforts had been to achieve a sufficiently high sensitivity and specificity for infrared imaging in order to make it useful as a prescreening device in selecting patients for referral for mammographic examination. It was thought that, if successful, the incorporation of this technology would result in a relatively small proportion of women having mammography (a technique that had caused concern at that time because of the carcinogenic effects of radiation). The Working Group indicated that the sensitivity and specificity of infrared imaging readings, with clinical data emanating from interinstitutional studies, were close to the corresponding results for physical examination and mammography. They noted that these three modalities selected different subgroups of breast cancers, and for this reason further evaluation of infrared imaging as a screening device in a controlled clinical trial was recommended.

### 25.7.1 Poor Study Design

While the Working Group describes in detail the importance of quality control of mammography, the entire protocol for infrared imaging was summarized in one paragraph and simply indicated that infrared imaging was conducted by a BCDDP trained technician. The detailed extensive results from this report, consisting of over 50 tables, included only one that referred to infrared imaging showing that it had detected only 41% of the breast cancers during the first screening while the residual were either normal or unknown. There is no breakdown as far as these two latter groups were concerned. Since 28% of the first screening and 32% of the second screening were picked up by mammography alone, infrared imaging was dropped from any further evaluation and consideration. The report stated that it was impossible to determine whether abnormal infrared images could be predictive of interval cancers (cancers developing between screenings) since they did not collect this data.

By the same token, the Working Group was unable to conclude, with their limited experience, whether the findings were related to the then available technology of infrared imaging or with its application. They did, however, conclude that the decision to dismiss infrared imaging should not be taken as a determination of the future of this technique, rather that the procedure continued to be of interest because it does not entail the risk of radiation exposure. In the Working Group’s final recommendation, they state that “infrared imaging does not appear to be suitable as a substitute for mammography for routine screening in the BCDDP.” The report admitted that several individual programs of the BCDDP had results that were more favorable than what was reported for the BCDDP as a whole. They encouraged investment in the development and testing of infrared imaging under carefully controlled study conditions and suggested that high priority be given to these studies. They noted that a few suitable sites appeared to be available within the BCDDP participants and proposed that developmental studies should be solicited from sites with sufficient experience.

### 25.7.2 Untrained Personnel and Protocol Violations

JoAnn Haberman, who was a participant in this project [72], provided further insight into the relatively simplistic regard assigned to infrared imaging during this program. The author reiterated that expertise in mammography was an absolute requirement for the awarding of a contract to establish a screening center. However, the situation was just the opposite with regard to infrared imaging — no experience was required at all. When the 27 demonstration project centers opened their doors, only 5 had any preexisting expertise in infrared imaging. Of the remaining screening centers, there was no experience at all in this technology. Finally, more than 18 months after the project had begun, the NCI established centers where radiologists and their technicians could obtain sufficient training in infrared imaging. Unfortunately, only 11 of the demonstration project directors considered this training of sufficient importance to send their technologists to learn proper infrared technique. The imaging sites also disregarded environmental controls. Many of the project sites were mobile imaging vans, which had poor heating and cooling capabilities and often kept their doors open in the front and rear to permit an easy flow of patients. This, combined with a lack of adherence to protocols and preimaging patient acclimation, lead to unreadable images.

In summary, with regard to infrared imaging, the BCDDP was plagued with problems and seriously flawed in five critical areas (1) The study was initiated with an incorrect premise that infrared imaging might replace mammography. A functional imaging procedure that detects metabolic thermovascular aberrations cannot replace a test that looks for specific areas of structural changes in the breast, (2) Completely untrained technicians were used to perform the scans, (3) The study used radiologists who had no experience or knowledge in reading infrared images, (4) Proper laboratory environmental controls were completely ignored. In fact, many of the research sites were mobile trailers with extreme variations in internal temperatures, (5) No standardized reading protocol had yet been established for infrared imaging. It was not until the early 1980s that established and standardized reading protocols were adopted. Considering these facts, the BCDDP could not have properly evaluated infrared imaging. Since the termination of the BCDDP, a considerable amount of published research has demonstrated the true value of this technology.

## 25.8 Mammography and Infrared Imaging

---

From a scientific standpoint, mammography and infrared imaging are completely different screening tests. As a structural imaging procedure, mammography cannot be compared to a functional imaging technology such as infrared imaging. While mammography attempts to detect architectural tissue shadows, infrared imaging observes for changes in the subtle metabolic milieu of the breast. Even though mammography and infrared imaging examine completely different aspects of the breast, research has been performed that allows for a statistical comparison of the two technologies. Since a review of the research on infrared imaging has been covered, data on the current state of mammography is presented.

In a study by Rosenberg, 183,134 screening mammograms were reviewed for changes in sensitivity due to age, breast density, ethnicity, and estrogen replacement therapy. Out of these screening mammograms 807 cancers were discovered at screening. The results showed that the sensitivity for mammography was 54% in women younger than 40, 77% in women aged 40–49, 78% in women aged 50–64, and 81% in women older than 64 years. Sensitivity was 68% in women with dense breasts and 74% in estrogen replacement therapy users [73].

Investigating the cumulative risk of a false-positive result in mammographic screening, Elmore and associates performed a 10-year retrospective study of 2400 women, 40 to 69 years of age. A total of 9762 mammograms were investigated. It was found that a woman had an estimated 49.1% cumulative risk of having a false-positive result after 10 mammograms. Even though no breast cancer was present, over one-third of the women screened were required to have additional evaluations [74].

In a review of the literature, Head investigated the sensitivity, specificity, positive predictive value, and negative predictive values for mammography and infrared imaging. The averaged reported performance

for mammography was: 86% sensitivity, 79% specificity, 28% positive predictive value, and 92% negative predictive value. For infrared imaging the averaged performance was: 86% sensitivity, 89% specificity, 23% positive predictive value, and 99.4% negative predictive value [75].

Pisano, along with a large investigational group, provided a detailed report on the Digital Mammographic Imaging Screening Trial (DMIST). The study investigated the diagnostic performance of digital versus film mammography in breast cancer screening. Both digital and film mammograms were taken on 42,760 asymptomatic women presenting for screening mammography. Data was gathered from 33 sites in the United States and Canada. Digital mammography was found to be more accurate in women under age 50 and in women whose breasts were radiographically dense. The sensitivity for both film and digital mammography was found to be 69% [76].

Keyserlingk and associates published a retrospective study reviewing the relative ability of clinical examinations, mammography, and infrared imaging to detect 100 new cases of ductal carcinoma *in situ*, stage I and 2 breast cancers. Results from the study found that the sensitivity for clinical examination alone was 61%, mammography alone was 66%, and infrared imaging alone was 83%. When suspicious and equivocal mammograms were combined the sensitivity was increased to 85%. A sensitivity of 95% was found when suspicious and equivocal mammograms were combined with abnormal infrared images. However, when clinical examination, mammography, and infrared images were combined a sensitivity of 98% was reached [77].

From a review of the cumulative literature database, it can be found that the average sensitivity and specificity for mammography is 80 and 79% respectively for women over the age of 50 [78–80]. A significant decrease in sensitivity and specificity is seen in women below this age. This same research also shows that mammography routinely misses interval cancers (cancers that form between screening exams) [81], which may be detected by infrared imaging. Taking into consideration all the available data, mammography leaves much to be desired as the current gold standard for breast cancer screening. As a stand alone screening procedure, it is suggested that mammography may not be the best choice. In the same light, infrared imaging should also not be used alone as a screening test. The two technologies are of a complimentary nature. Neither used alone are sufficient, but when combined each builds on the deficiencies of the other. In reviewing the literature it seems evident that a multimodal approach to breast cancer screening would serve women best. A combination of clinical examination, mammography, and infrared imaging would provide the greatest potential for breast conservation and survival.

## 25.9 Current Status of Breast Cancer Detection

---

Current first-line breast cancer detection strategy still depends essentially on clinical examination and mammography. The limitations of the former, with its reported sensitivity rate often below 65% [77,82] is well-recognized, and even the proposed value of self-breast examination is being contested [83]. While mammography is accepted as the most cost-effective imaging modality, its contribution continues to be challenged with persistent false-negative rates ranging up to 30% [73,76,84,85]; with decreasing sensitivity in younger patients and those on estrogen replacement therapy [73,86]. In addition, there is recent data suggesting that denser and less informative mammography images are precisely those associated with an increased cancer risk [86]. Echoing some of the shortcomings of the BCDDP7 concerning their study design and infrared imaging, Moskowitz indicated that mammography is also not a procedure to be performed by the inexperienced technician or radiologist [88].

With the current emphasis on earlier detection, there is now renewed interest in the parallel development of complimentary imaging techniques that can also exploit the precocious metabolic, immunological, and vascular changes associated with early tumor growth. While promising, techniques such as scintimammography [89], doppler ultrasound [90], and MRI [91] are associated with a number of disadvantages that include exam duration, limited accessibility, need of intravenous access, patient discomfort, restricted imaging area, difficult interpretation, and limited availability of the technology. Like ultrasound, they are more suited to use as second-line options to pursue the already abnormal screening evaluations. While

practical, this stepwise approach currently results in the nonrecognition, and thus delayed utilization of second-line technology in approximately 10% of established breast cancers [88]. This is consistent with a study published by Keyserlingk [77].

As an addition to the breast health screening process, infrared imaging has a significant role to play. Owing to infrared imaging's unique ability to image the metabolic aspects of the breast, extremely early warning signals (up to 10 years before any other detection method) have been observed in long-term studies. It is for this reason that an abnormal infrared image is the single most important marker of high risk for the existence of or future development of breast cancer. This, combined with the proven sensitivity, specificity, and prognostic value of the technology, places infrared imaging as one of the major frontline methods of breast cancer screening.

## 25.10 Future Advancements in Infrared Imaging

---

Modern high-resolution uncooled focal plane array cameras coupled with high speed computers running sophisticated image analysis software are commonplace in today's top infrared imaging centers. However, research in this field continues to produce technological advancements in image acquisition and digital processing.

Research is currently underway investigating the possible subtle alterations in the blood supply of the breast during the earliest stages of malignancy. Evidence suggests that there may be a normal vasomotor oscillation frequency in the arterial structures of the human body. It is theorized that there may be disturbances in this normal oscillatory rate when a malignancy is forming. Research using infrared detection systems capturing 200 frames per second with a sensitivity of 0.009 of a degree centigrade may be able to monitor alterations in this vasomotor frequency band.

Another unique methodology is investigating the possibility of using infrared emission data to extrapolate depth and location of a metabolic heat source within the body. In the case of cancer, the increased tissue metabolism resulting from rapid cellular multiplication and growth generates heat. With this new approach in infrared detection, it is theorized that an analysis based on an analogy to electrical circuit theory — termed the thermal-electric analog — may possibly be used to determine the depth and location of the heat source.

The most promising of all the advances in medical infrared imaging are the adaptations being used from military developments in the technology. Hardware advances in narrow band filtering hold promise in providing multispectral and hyperspectral images. One of the most intriguing applications of multispectral/hyperspectral imaging may include real-time intraoperative cytology. Investigations are also underway utilizing smart processing, also known as artificial intelligence. This comes in the form of post-image processing of the raw data from the infrared sensor array. Some of the leading-edge processing currently under study include automated target recognition (ATR), artificial neural networks (ANN), and threshold algorithms to mention only a few. The use of ATR and threshold algorithms are dependent on a reliable normative database. The images are processed based on what the system has learned as normal and compares the new image to that database. Unlike ATR and threshold algorithms, ANN uses data summation to produce pattern recognition. This is extremely important when it comes to the complex thermovascular patterns seen in infrared breast imaging. Ultimately, these advancements will lead to a decrease in operator dependence and a substantial increase in both objectivity and accuracy.

New breast cancer treatments are also exploring methods of targeting the angiogenic process. Due to a tumor's dependence on a constant blood supply to maintain growth, antiangiogenesis therapy is becoming one of the most promising therapeutic strategies and has been found to be pivotal in the new paradigm for consideration of breast cancer development and treatment [92]. The future may see infrared imaging and antiangiogenesis therapy combined as the state of the art in the biological assessment and treatment of breast cancer.

These and other new methodologies in medical infrared imaging are being investigated and may prove to be significant advancements. However, a great deal of research will need to be performed before new technologies can be adopted for medical use.

## 25.11 Conclusion

---

The large patient populations and long survey periods in many of the above clinical studies yield a high significance to the various statistical data obtained. This is especially true for the contribution of infrared imaging to early cancer diagnosis, as an invaluable marker of high-risk populations, and in therapeutic decision making.

Currently available high-resolution digital infrared imaging technology benefits greatly from enhanced image production, computerized image processing and analysis, and standardized image interpretation protocols. Over 40 years of research and 800 indexed papers encompassing well over 300,000 women participants has demonstrated infrared imaging's abilities in the early detection of breast cancer. Infrared imaging has distinguished itself as the earliest detection technology for breast cancer. It has the ability to signal an alarm that a cancer may be forming up to 10 years before any other procedure can detect it. In 7 out of 10 cases, infrared imaging will detect signs of a cancer before it is seen on a mammogram. Clinical trials have also shown that infrared imaging significantly augments the long-term survival rates of its recipients by as much as 61%. And when used as part of a multimodal approach (clinical examination, mammography, and infrared imaging) 95% of all early stage cancers will be detected. Ongoing research into the thermal characteristics of breast pathologies will continue to investigate the relationships between neoangiogenesis, chemical mediators, and the neoplastic process.

It is unfortunate, but many clinicians still hesitate to consider infrared imaging as a useful tool in spite of the considerable research database, steady improvements in both infrared technology and image analysis, and continued efforts on the part of the infrared imaging societies. This attitude may be due in part to the average clinician's unfamiliarity with the physical and biological basis of infrared imaging. The other methods of cancer investigations refer directly to topics of medical teaching. For instance, radiography and ultrasonography refer to structural anatomy. Infrared imaging, however, is based on thermodynamics and thermokinetics, which are unfamiliar to most clinicians; though man is experiencing heat production and exchange in every situation he undergoes or creates.

Considering the contribution that infrared imaging has demonstrated thus far in the field of early breast cancer detection, all possibilities should be considered for promoting further technical, biological, and clinical research along with the incorporation of the technology into common clinical use.

There is general consensus that earlier detection of breast cancer should result in improved survival. For the last two decades, first-line breast imaging has relied primarily on mammography. Despite better equipment and regulation, particularly with the recent introduction of digital mammography, variability in interpretation and tissue density can affect mammography accuracy. To promote earlier diagnosis, a number of adjuvant functional imaging techniques have recently been introduced, including Doppler ultrasound and gadolinium-enhanced magnetic resonance imaging (MRI) that can detect cancer-induced regional neovascularity. While valuable modalities, problems relating to complexity, accessibility, cost, and

in most cases the need for intravenous access make them unsuitable as components of a first-line imaging strategy.

In order to re-assess the potential contribution of infrared (IR) imaging as a first-line component of a multi-imaging strategy, using currently available technology, we will first review the history of its introduction and early clinical application, including the results of the Breast Cancer Demonstration Projects (BCDDP). We will then review the Ville Marie Multi-Disciplinary Breast Center's more recent experience with currently available high-resolution computerized IR technology to assess IR imaging both as a complement to clinical exam and mammography in the early detection of breast cancer and also as a tool to monitor the effects of pre-operative chemohormonotherapy in advanced breast cancer. Our goal is to show that high-resolution IR imaging provides additional safe, practical, cost effective, and objective information in both of these instances when produced by strict protocol and interpreted by sufficiently trained breast physicians. Finally, we will comment on its further evolution.

## 26.1 Historical Perspectives

---

### 26.1.1 Pre-Breast Cancer Detection Demonstration Projects Era

In 1961 in the *Lancet*, Williams and Handley [1] using a rudimentary hand-held thermopile, reported that 54 of 57 of their breast cancer patients were detectable by IR imaging, and "among these were cases in which the clinical diagnosis was in much doubt." The authors reported that the majority of these cancers had a temperature increase of 1 to 2°C, and that the IR imaging permitted excellent discrimination between benign and malignant processes. Their protocol at the Middlesex Hospital consisted of having the patient strip to the waist and be exposed to the ambient temperature for 15 min.

The authors demonstrated a precocious understanding of the significance of IR imaging by introducing the concept that increased cooling to 18°C further enhanced the temperature discrepancy between cancer and the normal breast. In a follow-up article the subsequent year, Handley [2] demonstrated a close correlation between the increased thermal pattern and increased recurrence rate. While only four of 35 cancer patients with a 1 to 2°C discrepancy recurred, five of the six patients with over 3°C rise developed recurrent cancer, suggesting already that the prognosis could be gauged by the amount of rise of temperature in the overlying skin.

In 1963, Lawson and Chughtai [3], two McGill University surgeons, published an elegant intra-operative study demonstrating that the increase in regional temperature associated with breast cancer was related to venous convection. This quantitative experiment added credence to Handley's suggestion that IR findings were related to both increased venous flow and increased metabolism.

In 1965, Gershon-Cohen [4], a radiologist and researcher from the Albert Einstein Medical Center, introduced IR imaging to the United States. Using a Barnes thermograph that required 15 min to produce a single IR image, he reported 4000 cases with a remarkable true positive rate of 94% and a false positive rate of 6%. This data was included in a review of the then current status of infrared imaging published in 1968 in *CA — A Cancer Journal for Physicians* [5]. The author, JoAnn Haberman, a radiologist from Temple University School of Medicine, reported the local experience with IR imaging, which produced a true positive rate of 84% compared with a concomitant true positive rate of 80% for mammography. In addition, she compiled 16,409 IR imaging cases from the literature between 1964 and 1968 revealing an overall true positive rate of 87% and a false positive rate of 13%.

A similar contemporary review compiled by Jones, consisting of nearly 70,000 cases, revealed an identical true positive rate of 85% and an identical false positive rate of 13%. Furthermore, Jones [6] reported on over 20,000 IR imagings from the Royal Marsden Hospital between 1967 and 1972, and noted that approximately 70% of Stage I and Stage II cancers and up to 90% of Stage III and Stage IV cancers had abnormal IR features. These reports resulted in an unbridled enthusiasm for IR imaging as a front-line detection modality for breast cancer.

Sensing a potential misuse of this promising but unregulated imaging modality, Isard made some sobering comments in 1972 [7] in a publication of the *American Journal of Roentengology*, where he

emphasized that, like other imaging techniques, IR imaging does not diagnose cancer but merely indicates the presence of an abnormality. Reporting his Radiology division's experience with 10,000 IR studies done concomitantly with mammography between 1967 and 1970, he reiterated a number of important concepts, including the remarkable stability of the IR image from year to year in the otherwise healthy patient, and the importance of recognizing any significant change. Infrared imaging detected 60% of occult cancers in his experience, vs. 80% with mammography. The combination of both these modalities increased the sensitivity by approximately 10%, thus underlining the complementarity of both of these processes, since each one did not always suspect the same lesion.

It was Isard's conclusion that, had there been a preliminary selection of his group of 4393 asymptomatic patients by IR imaging, mammography examination would have been restricted to the 1028 patients with abnormal IR imaging (23% of this cohort). This would have resulted in a cancer detection rate of 24.1 per 1000 mammographic examinations, as contrasted to the expected 7 per 1000 by mammographic screening. He concluded that since IR imaging is an innocuous examination, it could be utilized to focus attention upon asymptomatic women who should be examined more intensely.

In 1972, Gerald D. Dodd [8] of the Department of Diagnostic Radiology of the University of Texas presented an update on IR imaging in breast cancer diagnosis at the Seventh National Cancer Conference sponsored by the National Cancer Society, and the National Cancer Institute. He also suggested that IR imaging would be best employed as a screening agent for mammography and proposed that in any general survey of the female population age 40 and over, 15–20% would have positive IR imaging and would require mammograms. Of these, approximately 5% would be recommended for biopsy. He concluded that IR imaging would serve to eliminate 80–85% of the potential mammograms. Reporting the Texas Medical School's experience with IR imaging, he reiterated that IR was capable of detecting approximately 85% of all breast cancers. The false positive rate of 15–20% did not concern the author, who stated that these were false positives only in the sense that there was no corroborative evidence of breast cancer at the time of the examination and that they could serve to identify a high-risk population.

Feig et al. [9], reported the respective abilities of clinical exam, mammography, and IR imaging to detect breast cancer in 16,000 self-selected women. While only 39% of the initial series of overall established cancer patients had an abnormal IR imaging, this increased to 75% in his later cohort, reflecting an improved methodology. Of particular interest was the ability of IR imaging to detect 54% of the smallest tumors, four times that of clinical examination. This potential important finding was not elaborated, but it could reflect IR's ability to detect vascular changes that are sometimes more apparent at the initiation of tumor genesis. The authors suggested that the potential of IR imaging to select high-risk groups for follow-up screening merited further investigation.

Wallace [10] presented an update on IR imaging of the breast to another contemporary Cancer Conference sponsored by the American College of Radiology, the American Cancer Society, and the Cancer Control Programme of the National Cancer Institute. The analysis suggested that the incidence of breast cancer detection per 1000 screenees could increase from 2.72 when using mammography to 19 when using IR imaging. He then underlined that IR imaging poses no radiation burden on the patient, requires no physical contact, and, being an innocuous technique, could concentrate the sought population by a significant factor, selecting those patients that required further investigation. He concluded that "the resulting IR image contains only a small amount of information as compared to the mammogram, so that the reading of the IR image is a substantially simpler task."

Unfortunately, this rather simplistic and cavalier attitude toward the acquisition and interpretation of IR imaging was widely prevalent when it was hastily added to the BCDDP, which was just getting underway. Rather than assess, in a controlled manner, its potential as a complementary first-line detection modality, it was hastily introduced into the BCDDP as potential replacement for mammography and clinical exam.

### **26.1.2 The Breast Cancer Detection Demonstration Projects Era**

A detailed review of the Report of the Working Group of the BCDDP is essential to understand the subsequent evolution of IR imaging [11]. The scope of this project was issued by the National Cancer

Institute (NCI) on March 26, 1973, with six objectives, the second being to determine if a negative IR imaging was sufficient to preclude the use of clinical examination and mammography in the detection of breast cancer. The Working Group, reporting on results of the first 4 years of this project, gave a short history regarding IR imaging in breast cancer detection. They reported that as of the 1960s, there was intense interest in determining the suitability of IR imaging for large-scale applications, and mass screening was one possibility. The need for technological improvement was recognized and the authors stated that efforts had been made to refine the technique. One of the important objectives behind these efforts had been to achieve a sufficiently high sensitivity and specificity for IR imaging under screening conditions to make it useful as a prescreening device in selecting patients who would then be referred for mammographic examination. It was thought that if successful, this technology would result in a relatively small proportion of women having mammography, a technique that caused concern because of the carcinogenic effects of radiation. The Working Group indicated that the sensitivity and specificity of IR imaging readings from clinical data emanating from interinstitutional studies were close to the corresponding results for physical examination and for mammography. While they noted that these three modalities selected different subgroups of breast cancers, further evaluation of IR imaging as a potential stand-alone screening device in a controlled clinical trial was recommended.

The authors of the BCDDP Working Group generated a detailed review of mammography and efforts to improve its quality control in image quality and reduction in radiation. They recalled that in the 1960s, the Cancer Control Board of the U.S. Public Health Service had financed a national mammography training programme for radiologists and their technologists. Weekly courses in mammography were taught at approximately ten institutions throughout the country with material supplied by the American College of Radiology. In 1975, shortly after the beginning of this project, the NCI had already funded seven institutions in the United States in a 3-year effort aimed at reorienting radiologists and their technologists in more advanced mammographic techniques and interpretation for the detection of early breast cancer.

In the interim, the American College of Radiology and many interested mammographers and technologists had presented local postgraduate refresher courses and workshops on mammography. Every year for the previous 16 years, the American College of Radiology had supported, planned and coordinated week-long conferences and workshops aimed at optimizing mammography to promote the earlier detection and treatment of breast cancer. It was recognized that the well-known primary and secondary mammographic signs of a malignant condition, such as ill-defined mass, skin thickening, skin retraction, marked fibrosis and architectural distortion, obliteration of the retromammary space, and enlarged visible axillary lymph nodes, could detect an established breast cancer. However, the authors emphasized that more subtle radiographic signs that occur in minimal, clinically occult, and early cancers, such as localized punctate calcifications, focal areas of duct prominence, and minor architectural distortion, could lead to an earlier diagnosis even when the carcinoma was not infiltrating, which was a rare finding when previous mammographic techniques were used.

The authors reiterated that the reproduction of early mammography signs required a constant high-quality technique for fine image detail, careful comparison of the two breasts during interpretation, and the search for areas of bilateral, parenchymal asymmetry that could reflect underlying cancer. The BCDDP Working Group report stated that mammographies were conducted by trained technicians and that, while some projects utilized radiological technicians for the initial interpretation, most used either a radiologist or a combination of technician and radiologist. Quality control for mammography consisted of reviews by the project radiologists and site visits by consultants to identify problems in procedures and the quality of the films.

On the other hand, the entire protocol for IR imaging within this study was summarized in one paragraph, and it indicated that IR imaging was conducted by a BCDDP trained technician. Initial interpretation was made mostly by technicians; some projects used technicians plus radiologists and a few used radiologists and/or physicians with other specialties for all readings. Quality control relied on review of procedures and interpretations by the project physicians. Positive physical exams and mammographies were reported in various degrees of certainty about malignancy or as suspicious-benign; IR imaging was reported simply as normal or abnormal. While the protocol for the BCDDP required that the three

clinical components of this study (physical examination, IR imaging, and mammography) be conducted separately, and initial findings and recommendations be reported independently, it was not possible for the Working Group to assess the extent to which this protocol was adhered to or to evaluate the quality of the examinations.

The detailed extensive results from this Working Group report consisted of over 50 tables. There was, however, only one table that referred to IR imaging, showing that it had detected 41% of the breast cancers during the first screening, while the residuals were either normal or unknown. There is no breakdown as far as these two latter groups were concerned. Since 28% of the first screening and 32% of the second screening were picked up by mammography alone, IR imaging was dropped from any further evaluation and consideration. The report stated that it was impossible to determine whether abnormal IR imaging could be predictive of interval (developing between screenings) cancers, since these data were not collected.

By the same token, the Working Group was unable to conclude, with their limited experience, whether the findings were related to the then existing technology of IR imaging or with its application. They did, however, indicate that the decision to dismiss IR imaging should not be taken as a determination of the future of this technique, rather that the procedure continued to be of interest because it does not entail the risk of radiation exposure. In the Working Group's final recommendation, they state that "infrared imaging does not appear to be suitable as a substitute for mammography for routine screening in the BCDDP" but could not comment on its role as a complementary modality. The report admitted that several individual programs of the BCDDP had results that were more favorable than for the BCDDP as a whole. They also insisted that high priority be given to development and testing of IR imaging under carefully controlled study conditions. They noted that a few suitable sites appeared to be available among the BCDDP and proposed that developmental studies should be solicited from the sites with sufficient experience.

Further insight into the inadequate quality control assigned to IR imaging during this program was provided by Haberman, a participant in that project [12]. The author reiterated that, while proven expertise in mammography was an absolute requirement for the awarding of a contract to establish a Screening Center, the situation was just the opposite as regards to IR imaging. As no experience was required, when the 27 demonstration projects opened their doors, only five of the centers had pre-existing expertise in IR imaging. Of the remaining screening centers, there was no experience at all in this technology. Finally, more than 18 months after the BCDDP project had begun operating, the NCI, recognizing this problem, established centers where radiologists and their technicians could obtain further training in IR imaging. Unfortunately, only 11 of the demonstration project directors considered this training of sufficient importance to send their technologists. In some centers, it was reported that there was no effort to cool the patient prior to examination. In other centers, there was complete lack of standardization, and a casual attitude prevailed with reference to interpretation of results. While quality control of this imaging technology could be considered lacking, it was nevertheless subjected to the same stringent statistical analysis as was mammography and clinical breast examination.

### **26.1.3 Post-Breast Cancer Detection Demonstration Projects Era**

Two small-scale studies carried out in the 1970s by Moskowitz [13] and Threatt [14] reported on the sensitivity and reliability of IR imaging. Both used "experts" to review the images of breast cancer patients. While Moskowitz excluded unreadable images, data from Threatt's study indicated that less than 30% of the images produced were considered good, with the rest being substandard. Both these studies produced poor results, inconsistent with numerous previous multicenter trials, particularly that of Stark [15] who, 16 years earlier, reported an 81% detection rate for preclinical cancers.

Threatt noted that IR imaging demonstrated an increasing accuracy as cancers increased in size or aggressiveness, as did the other testing modalities (i.e., physical examination and mammography). The author also suggested that computerized pattern recognition would help solve the reproducibility problems sometimes associated with this technology and that further investigation was warranted. Moskowitz also suggested that for IR imaging to be truly effective as a screening tool, there needed to be more objective means of interpretation. He proposed that this would be much facilitated by computerized evaluation.

In a frequently cited article, Sterns and Cardis [16] reviewed their group's limited experience with IR in 1982. While there were only 11 cancer cases in this trial, they were concerned about a sensitivity of 60% and a false positive rate of IR of 12%. While there was no mention of training, they concluded, based on a surprisingly low false positive rate of clinical exam of only 1.4%, that IR could not be recommended for breast diagnosis or as an indication for mammography.

Thirteen years later, reviewing the then status of breast imaging, Moskowitz [17] challenged the findings of the recent Canadian National Breast Screening Study (NBSS) that questioned the value of mammography, much in the same way that the Working Group of the BCDDP questioned IR imaging 20 years previously. Using arguments that could have qualified the disappointing results of the IR imaging used in the BCDDP study, the author explained the poor results of mammography in the NBSS on the basis of inadequate technical quality. He concluded that only 68% of the women received satisfactory breast imaging.

In addition to the usual causes of poor technical quality, failure to use the medial lateral oblique view resulted in exclusion of the tail of Spence and of much of the upper outer quadrant in many of the subjects screened. There was also a low interobserver agreement in the reading of mammographies, which resulted in a potential diagnostic delay. His review stated that of all noncontrast, nondigital radiological procedures, mammography required the greatest attention to meticulous detail for the training of technologists, selection of the film, contrast monitoring of processing, choosing of equipment, and positioning of the patient. For mammography to be of value, it required dedicated equipment, a dedicated room, dedicated film, and the need to be performed and interpreted by dedicated people. Echoing some of the criticisms that could be pertinent to the BCDDP's use of IR imaging, he indicated that mammography is not a procedure to be performed by the untutored. In rejecting any lack of quality control of IR imaging during the BCDDP studies by stating that "most of the investigators in the BCDDP did undergo a period of training." The author once again suggested that the potential of IR imaging would only increase if there was better standardization of technology and better-designed clinical trials.

Despite its initial promise, this challenge was not taken up by the medical community, who systematically lost interest in this technique, primarily due to the nebulous BCDDP experience. Nevertheless, during the 1980s, a number of isolated reports continued to appear, most emphasizing the risk factors associated with abnormal IR imaging. In *Cancer* in 1980, Gautherie and Gros [18] reported their experience with a group of 1245 women who had a mildly abnormal infrared image along with either normal or benign disease by conventional means, including physical exam, mammography, ultrasonography, and fine needle aspiration or biopsy. They noted that within 5 years, more than one-third of this group had histologically confirmed cancers. They concluded that IR imaging is useful not only as a predictor of breast cancer risk but also to identify the more rapidly growing neoplasms.

The following year, Amalric et al. [19], expanded on this concept by reporting that 10 to 15% of patients undergoing IR imaging will be found to be mildly abnormal when the remainder of the examination is essentially unremarkable. They noted that among these "false positive" cases, up to 38% will eventually develop breast cancer when followed closely. In 1981, Mariel [20] carried out a study in France on 655 patients and noted an 82% sensitivity. Two years later, Isard [21] discussed the unique characteristics and respective roles of IR imaging and ultrasonography and concluded that, when used in conjunction with mammography in a multi-imaging strategy, their potential advantages included enhanced diagnostic accuracy, reduction of unnecessary surgery, and improved prognostic ability. The author emphasized that neither of these techniques should be used as a sole screening modality for breast cancer in asymptomatic women, but rather as a complementary modality to mammography.

In 1984, Nyirjesy [22] reported in *Obstetrics and Gynecology* a 76% sensitivity for IR imaging of 8767 patients. The same year, Bothmann [23] reported a sensitivity of 68% from a study carried out in Germany on 2702 patients. In 1986, Useki [24] published the results of a Japanese study indicating an 88% sensitivity.

Despite newly available IR technology, due in large part to military research and development, as well as compelling statistics of over 70,000 documented cases showing the contribution of functional IR imaging in a hitherto structurally based strategy to detect breast cancer, few North American centers have shown an interest, and fewer still have published their experience. This is surprising in view of the current consensus

regarding the importance of vascular-related events associated with tumor initiation and growth that finally provide a plausible explanation for the IR findings associated with the early development of smaller tumors. The questionable results of the BCDDP and a few small-scale studies are still being referred to by a dwindling authorship that even mention the existence of this imaging modality. This has resulted in a generation of imagers that have neither knowledge of nor training in IR imaging. However, there are a few isolated centers that have continued to develop an expertise in this modality and have published their results.

In 1993, Head et al. [25] reported that improved images of the second generation of IR systems allowed more objective and quantitative visual analysis. They also reported that growth-rate-related prognostic indicators were strongly associated with the IR results [26]. In 1996, Gamagami [27] studied angiogenesis by IR imaging and reported that hypervascularity and hyperthermia could be shown in 86% of nonpalpable breast cancers. He also noted that in 15% of these cases, this technique helped to detect cancers that were not visible on mammography.

The concept of angiogenesis, suggested by Gamagami as an integral part of early breast cancer, was reiterated in 1996 by Guidi and Schnitt [28], whose observations suggested that angiogenesis is an early event in the development of breast cancer. They noted that it may occur before tumor cells acquire the ability to invade the surrounding stroma and even before there is morphologic evidence of an *in situ* carcinoma.

In contemporary publications, Anbar [29,30], using an elegant biochemical and immunological cascade, suggested that the empirical observation that small tumors capable of producing notable IR changes could be due to enhanced perfusion over a substantial area of breast surface via tumor-induced nitric oxide vasodilatation. He introduced the importance of dynamic area telethermometry to validate IR's full potential.

Parisky and his colleagues working out of six radiology centers [31] published an interesting report in Radiology in 2003 relating to the efficacy of computerized infrared imaging analysis of mammographically suspicious lesions. They reported a 97% sensitivity, a 14% specificity, and a 95% negative predictive value when IR was used to help determine the risk factors relating to mammographically noted abnormal lesions in 875 patients undergoing biopsy. They concluded that infrared imaging offers a safe, noninvasive procedure that would be valuable as an adjunct to mammography determining whether a lesion is benign or malignant.

## **26.2 The Ville Marie Multi-Disciplinary Breast Center Experience with High-Resolution Digital Infrared Imaging to Detect and Monitor Breast Cancer**

---

### **26.2.1 Infrared Imaging as Part of a First-Line Multi-Imaging Strategy to Promote Early Detection of Breast Cancer**

There is still a general consensus that the crucial strategy for the first-line detection of breast cancer depends essentially on clinical examination and mammography. Limitation of the former, with its reported sensitivity rate below 65% is well recognized [32], and even the proposed value of breast self-examination is now being contested [33]. With the current emphasis on earlier detection, there is an increasing reliance on better imaging. Mammography is still considered as our most reliable and cost-effective imaging modality [17]. However, variable inter-reader interpretation [34] and tissue density, now proposed as a risk factor itself [35] and seen in both younger patients and those on hormonal replacement [36], prompted us to reassess currently available IR technology spearheaded by military research and development, as a first-line component of a multi-imaging breast cancer detection strategy (Figure 26.1).

This modality is capable of quantifying minute temperature variations and qualifying abnormal vascular patterns, probably associated with regional angiogenesis, neovascularization (Figure 26.2), and nitric oxide-induced regional vasodilatation [29], frequently associated with tumor initiation and progression, and potentially an early predictor of tumor growth rate [26,28]. We evaluated a new fully integrated high-resolution computerized IR imaging station to complement mammography units. To validate its

FIGURE 26.1 Ville Marie breast center: clinical and multi-imaging breast cancer detection strategy.

reported ability to help detect early tumor-related regional metabolic and vascular changes [27], we limited our initial review to a series of 100 successive cases of breast cancer who filled the following three criteria (a) minimal evaluation included a clinical exam, mammography, and IR imaging; (b) definitive surgical management constituted the preliminary therapeutic modality carried out at one of our affiliated institutions; and (c) the final staging consisted of either noninvasive cancer ( $n = 4$ ), Stage I ( $n = 42$ ), or Stage II ( $n = 54$ ) invasive breast cancer.

While 94% of these patients were referred to our Multidisciplinary Breast Center for the first time, 65% from family physicians and 29% from specialists, the remaining 6% had their diagnosis of breast cancer at a follow-up visit. Age at diagnosis ranged from 31 to 84 years, with a mean age of 53. The mean histologic tumor size was 2.5 cm. Lymphatic, vascular, or neural invasion was noted in 18% of patients; and concomitant noninvasive cancer was present, along with the invasive component, in 64%. One-third of the 89 patients had axillary lymph node dissection, one-third had involved nodes, and 38% of the tumors were histologic Grade III.

While most of these patients underwent standard four-view mammography, with additional views when indicated, using a GE DMR apparatus at our center, in 17 cases we relied on recent and adequate quality outside films. Mammograms were interpreted by our examining physician and radiologist, both having access to the clinical findings. Lesions were considered suspicious if either of them noted findings indicative of carcinoma. The remainder were considered either contributory but equivocal or nonspecific. A nonspecific mammography required concordance with our examining physician, radiologist, and the authors.

**FIGURE 26.2** (See color insert following page 29-16.) (a) Tumor angiogenesis. (b) High nuclear grade ductal carcinoma *in situ* with numerous blood vessels (angiogenesis) (Tabar). (c) Invasive ductal carcinoma with central necrosis and angiogenesis (Tabar).

Our integrated IR station at that time consisted of a scanning-mirror optical system containing a mercury-cadmium-telluride detector (Bales Scientific, CA) with a spatial resolution of 600 optical lines, a central processing unit providing multitasking capabilities, and a high-resolution color monitor capable of displaying  $1024 \times 768$  resolution points and up to 110 colors or shades of gray per image. IR imaging took place in a draft-free thermally controlled room, maintained at between 18 and 20°C, after a 5 min equilibration period during which the patient sat disrobed with her hands locked over her head. We requested that the patients refrain from alcohol, coffee, smoking, exercise, deodorant, and lotions 3 h prior to testing.

Four images (an anterior, an under-surface, and two lateral views), were generated simultaneously on the video screen. The examining physician would digitally adjust them to minimize noise and enhance

**TABLE 26.1** Ville Marie Infrared (IR) Grading Scale*Abnormal signs*

1. Significant vascular asymmetry.<sup>a</sup>
2. Vascular anarchy consisting of unusual tortuous or serpiginous vessels that form clusters, loops, abnormal arborization, or aberrant patterns.
3. A 1°C focal increase in temperature ( $\Delta T$ ) when compared to the contralateral site and when associated with the area of clinical abnormality.<sup>a</sup>
4. A 2°C focal  $\Delta T$  versus the contralateral site.<sup>a</sup>
5. A 3°C focal  $\Delta T$  versus the rest of the ipsilateral breast when not present on the contralateral site.<sup>a</sup>
6. Global breast  $\Delta T$  of 1.5°C versus the contralateral breast.<sup>a</sup>

*Infrared scale*

IR1 = Absence of any vascular pattern to mild vascular symmetry.

IR2 = Significant but symmetrical vascular pattern to moderate vascular asymmetry, particularly if stable.

IR3 = One abnormal sign.

IR4 = Two abnormal signs.

IR5 = Three abnormal signs.

<sup>a</sup>Unless stable on serial imaging or due to known non-cancer causes (e.g., abscess or recent benign surgery).

Infrared Imaging takes place in a draft free, thermally controlled room maintained between 18 and 20°C, after a 5 min equilibration period during which the patient is disrobed with her hands locked over her head. Patients are asked to refrain from alcohol, coffee, smoking, exercise, deodorant, and lotions 3 h prior to testing.

detection of more subtle abnormalities prior to exact on-screen computerized temperature reading and IR grading. Images were then electronically stored on retrievable laser discs. Our original Ville Marie grading scale relies on pertinent clinical information, comparing IR images of both breasts with previous images. An abnormal IR image required the presence of at least one abnormal sign (Table 26.1). To assess the false-positive rate, we reviewed, using similar criteria, our last 100 consecutive patients who underwent an open breast biopsy that produced a benign histology. We used the Carefile Data Analysis Program to evaluate the detection rate of variable combinations of clinical exam, mammography, and IR imaging.

Of this series, 61% presented with a suspicious palpable abnormality, while the remainder had either an equivocal (34%) or a nonspecific clinical exam (5%). Similarly, mammography was considered suspicious for cancer in 66%, while 19% were contributory but equivocal, and 15% were considered nonspecific. Infrared imaging revealed minor variations (IR-1 or IR-2) in 17% of our patients while the remaining 83% had at least one (34%), two (37%), or three (12%) abnormal IR signs. Of the 39 patients with either a nonspecific or equivocal clinical exam, 31 had at least one abnormal IR sign, with this modality providing pertinent indication of a potential abnormality in 14 of these patients who, in addition, had an equivocal or nonspecific mammography.

Among the 15 patients with a nonspecific mammography, there were 10 patients (mean age of 48; 5 years younger than the full sample) who had an abnormal IR image. This abnormal finding constituted a particularly important indicator in six of these patients who also had only equivocal clinical findings. While 61% of our series presented with a suspicious clinical exam, the additional information provided by the 66 suspicious mammographies resulted in an 83% detection rate. The combination of only suspicious mammograms and abnormal IR imaging increased the sensitivity to 93%, with a further increase to 98% when suspicious clinical exams were also considered (Figure 26.3).

The mean histologically measured tumor size for those cases undetected by mammography was 1.66 cm. while those undetected by IR imaging averaged 1.28 cm. In a concurrent series of 100 consecutive eligible patients who had an open biopsy that produced benign histology, 19% had an abnormal IR image while 30% had an abnormal pre-operative mammography that was the only indication for surgery in 16 cases.

**FIGURE 26.3** Relative contribution of clinical exam, mammography, and IR imaging to detect breast cancer in the Ville Marie Breast Center series. In this series, adding infrared imaging to both suspicious and equivocal mammographies increased the detection rate. (1) Suspicious clinical exam; (2) Suspicious mammography; (3) Suspicious clinical exam or suspicious mammography; (4) Abnormal infrared imaging; (5) Suspicious or equivocal mammography; (6) Abnormal infrared imaging or suspicious mammography; (7) Abnormal infrared imaging or equivocal or suspicious mammography; and (8) Abnormal infrared imaging or suspicious mammography or suspicious clinical exam.

The 83% sensitivity of IR imaging in this series is higher than the 70% rate for similar Stage I and II patients tested from the Royal Marsden Hospital two decades earlier [6]. Although our results might reflect an increased index of suspicion associated with a referred population, this factor should apply equally to both clinical exam and mammography, maintaining the validity of our evaluation. Additional factors could include our standard protocol, our physicians' prior experience with IR imaging, their involvement in both image production and interpretation, as well as their access to much improved image acquisition and precision (Figure 26.4).

While most previous IR cameras had 8-bit (one part in 256) resolution, current cameras are capable of one part in 4096 resolution, providing enough dynamic range to capture all images with 0.05°C discrimination without the need for range switching. With the advancement of video display and enhanced gray and colors, multiple high-resolution views can be compared simultaneously on the same monitor. Faster computers now allow processing functions such as image subtraction and digital filtering techniques for image enhancement. New algorithms provide soft tissue imaging by characterizing dynamic heat-flow patterns. These and other innovations have made vast improvements in the medical IR technology available today.

The detection rate in a series where half the tumors were under 2 cm, would suggest that tumor-induced thermal patterns detected by currently available IR technology are more dependent on early vascular and metabolic changes. These changes possibly are induced by regional nitric oxide diffusion and ferritin interaction, rather than strictly on tumor size [29]. This hypothesis agrees with the concept that angiogenesis may precede any morphological changes [28]. Although both initial clinical exam and mammography are crucial in signaling the need for further investigation, equivocal and nonspecific findings can still result in a combined delayed detection rate of 10% [17].

When eliminating the dubious contribution of our 34 equivocal clinical exams and 19 equivocal mammograms, which is disconcerting to both physician and patient, the alternative information provided by IR imaging increased the index of concern of the remaining suspicious mammograms by 27% and the combination of suspicious clinical exams or suspicious mammograms by 15% (Figure 26.3). An imaging-only strategy, consisting of both suspicious and equivocal mammography and abnormal IR imaging, also detected 95% of these tumors, even without the input of the clinical exam. Infrared imaging's most tangible contribution in this series was to signal an abnormality in a younger cohort of breast cancer patients who had noncontributory mammograms and also nonspecific clinical exams who conceivably would not have been passed on for second-line evaluation.

**FIGURE 26.4** (See color insert.) (a) A 46-year old patient: Lump in the upper central area of the right breast. *Infrared imaging* (A): Significant vascular asymmetry (SVA) in the upper central area of the right breast (IR-3). *Mammography* (B): Corresponding speculated opacity. *Surgical histology*: 2 cm infiltrating ductal carcinoma with negative sentinel nodes. (b) A 44-year old patient. *Infrared imaging* (A): Revealed a significant vascular asymmetry in the upper central and inner quadrants of the right breast with a  $\Delta T$  of 1.8°C (IR-4.8). *Corresponding mammography* (B): Reveals a spiculated lesion in the upper central portion of the right breast. *Surgical histology*: 0.7 cm infiltrating ductal carcinoma. Patient underwent adjuvant brachytherapy.

While 17% of these tumors were undetected by IR imaging, either due to insufficient production or detection of metabolic or vascular changes, the 19% false positive rate in histologically proven benign conditions, in part a reflection of our current grading system, suggests sufficient specificity for this modality to be used in an adjuvant setting.

Our validation of prior data would also suggest that IR imaging, based more on process than structural changes and requiring neither contact, compression, radiation, nor venous access, can provide pertinent and practical complementary information to both clinical exam and mammography, our current first-line detection modalities. Quality-controlled abnormal IR imaging heightened our index of suspicion

**FIGURE 26.4** (See color insert.) (c) A 52-year old patient presented with a mild fullness in the lower outer quadrant of the right breast. *Infrared imaging* (A): Left breast (B): right breast reveals extensive significant vascular asymmetry with a  $\Delta T$  of  $1.35^{\circ}\text{C}$  (IR-5.3). A 2 cm cancer was found in the lower outer area of the right breast. (d) A 37-year old patient. *Infrared image* (A): Significant vascular asymmetry in the upper inner quadrant of the left breast with a  $\Delta T$  of  $1.75^{\circ}\text{C}$  (IR-4) (mod IR-4.75). *Mammography* (B): Corresponding spiculated lesion. *Ultrasound* (C): 6 mm lesion. *Surgical histology*: 0.7 cm infiltrating ductal carcinoma.

**FIGURE 26.4** (See color insert.) (e) An 82-year old patient. *Infrared imaging anterior view.* Significant vascular asymmetry and a  $\Delta T$  of 1.90°C (IR-4) in the left subareolar area. *Corresponding mammography:* (not included) asymmetrical density in the left areolar area. *Surgical histology:* Left subareolar 1 cm infiltrating ductal carcinoma.(f) A 34-year old patient with a palpable fullness in the supra-areolar area of the right breast. *Infrared imaging (A):* Extensive significant vascular asymmetry and a  $\Delta T$  of 1.3°C in the right supra areolar area (IR-4) (mod IR-5.3). *Mammography (B):* Scattered and clustered central microcalcifications. *Surgical histology:* After total right mastectomy and TRAM flap: multifocal DCIS and infiltrating ductal CA centered over a 3 cm area of the supra areolar area.

in cases where clinical or mammographic findings were equivocal or nonspecific, thus signaling further investigation rather than observation or close monitoring (Figure 26.5) and to minimize possibility of further delay (Figure 26.6).

### 26.2.2 Preliminary Evaluation of Digital High-Resolution Functional Infrared Imaging to Monitor Pre-Operative Chemohormonotherapy-Induced Changes in Neo-Angiogenesis in Patients with Advanced Breast Cancer

Approximately 10% of our current breast cancer patients present with sufficient tumor load to be classified as having locally advanced breast cancer (LABC). This heterogeneous subset of patients, usually diagnosed

**FIGURE 26.5** (See color insert.) (a) A 48-year old patient *Infrared imaging* (A): Significant vascular asymmetry and a  $\Delta T$  of  $0.8^{\circ}\text{C}$  (IR-3) in the lower inner quadrant of the left breast. *Corresponding mammography* (B): A nonspecific density. *Surgical histology*: 1.6 cm left lower inner quadrant infiltrating ductal carcinoma. (b) A 40-year old patient. *Infrared imaging* (A): left breast (B) right breast: focal hot spot in the right subareolar area on a background of increased vascular activity with a  $\Delta T$  of  $1.1^{\circ}\text{C}$  (IR-4). *Corresponding mammography* (C): Reveals dense tissue bilaterally. *Surgical histology*: reveals a 1 cm right infiltrating ductal carcinoma and positive lymph nodes.

with either stage T3 or T4 lesions without evidence of metastasis, and thus judged as potential surgical candidates, constitutes a formidable therapeutic challenge. Pre-operative or neo-adjuvant chemotherapy (PCT), hormonotherapy or both, preferably delivered within a clinical trial, is the current favored treatment strategy.

**FIGURE 26.5** (See color insert.) (c) A 51-year old patient. *Infrared imaging* (A): Significant vascular asymmetry and a  $\Delta T$  of 2.2°C (IR-5) in the upper central area of the left breast. *Corresponding mammography* (B): Mild scattered densities. *Surgical histology*: 2.5 cm infiltrating ductal carcinoma in the upper central area of the left breast. (d) A 44-year old patient. *Infrared imaging* (A): Significant vascular asymmetry and a  $\Delta T$  of 1.58°C (IR-4) in the upper inner quadrant of the left breast. *Corresponding mammography* (B): A nonspecific corresponding density. *Surgical histology*: A 0.9 cm left upper inner quadrant infiltrating ductal carcinoma.

Pre-operative chemotherapy offers a number of advantages, including ensuring improved drug access to the primary tumor site by avoiding surgical scarring, the possibility of complete or partial tumor reduction that could down-size the extent of surgery and also the ability to better plan breast reconstruction when the initial tumor load suggests the need for a possible total mastectomy. In addition, there is sufficient data to suggest that the absence of any residual tumor cells in the surgical pathology specimen following PTC confers the best prognosis, while those patients achieving at least a partial clinical response as measured by at least a 50% reduction in the tumor’s largest diameter often can aspire to a better survival than nonresponders [37]. While current clinical parameters do not always reflect actual PCT-induced tumor changes, there is sufficient correlation to make measuring the early clinical response to PTC an important element in assessing the efficacy of any chosen regimen. Unfortunately, the currently available conventional

**FIGURE 26.5** (See color insert.) (e) A 45-year old patient with a nodule in central area of left breast. *Infrared imaging* (A): Extensive significant vascular asymmetry (SVA) in the central inner area of the left breast with a  $\Delta T$  of  $0.75^\circ\text{C}$  (IR-3) (mod IR-4.75). *Mammography* (B): Non-contributory. *Surgical histology*: 1.5 cm infiltrating ductal carcinoma with necrosis in the central inner area and 3 + axillary nodes. (f) A 51-year old patient. *Infrared imaging* (A): Extensive significant vascular asymmetry and a  $\Delta T$  of  $2.2^\circ$  (IR-5) (mod IR-6.2) in the upper central area of the left breast. *Corresponding mammography* (B) scattered densities. *Surgical histology*: 2.5 cm infiltrating ductal carcinoma in the upper central area of the left breast.

monitoring tools, such as palpation combined with structural/anatomic imaging such as mammography and ultrasound have a limited ability to precisely measure the initial tumor load, and even less to reflect the effect of PCT [34].

These relatively rudimentary tools are dependent on often-imprecise anatomical and structural parameters. A more effective selection of often quite aggressive therapeutic agents and ideal duration of their use could be enhanced by the introduction of a convenient, safe, and accessible modality that could provide an alternative and serial measurement of their therapeutic efficacy.

There is thus currently a flurry of interest to assess the potential of different functional imaging modalities that could possibly monitor tumor changes looking at metabolic and vascular features to fill the void. Detecting early metabolic changes associated early tumor initiation and growth using positron emission

FIGURE 26.6 (See color insert.) (a) A 66-year old patient. Initially seen 2 years prior to diagnosis of left breast cancer for probable fibrocystic disorder (FCD) and scattered cysts, mostly on the left side. *Initial infrared imaging* (A): Extensive significant vascular asymmetry left breast and a near global  $\Delta T$  of  $1.4^{\circ}\text{C}$  (IR-4) (Mod IR: 5.4). *Initial mammography* (B): Scattered opacities and ultrasound and cytologies were consistent with FCD. Two years later a 1.7 cm cancer was found in the central portion of the left breast.

tomography [38,39], MRI, and Sestamibi scanning are all potential candidates to help monitor PCT-related effects. Unfortunately, they are all hampered by limited access for serial use, duration of the exam, costs, and the need of intravenous access. High-resolution digital infrared imaging, on the other hand, a convenient functional imaging modality free of these inconveniences and requiring neither radiation, nuclear material, contact, nor compression, can be used repeatedly without safety issues. There is ample data indicating its ability to effectively and reliably detect, in a multi-imaging strategy, neoangiogenesis

**FIGURE 26.6** (See color insert.) (b) A 49-year old patient. *Infrared imaging* 1997 (A): Significant vascular asymmetry in the upper central aspect of the left breast (IR-3) *Corresponding mammography* 1997 (B): Dense tissue (contd. 6B2) (c) Patient presents 2 years later with a lump in the upper central portion of the left breast. *Corresponding infrared imaging* (C): Still reveals significant vascular asymmetry and a  $\Delta T$  of  $0.7^{\circ}\text{C}$  (IR-3) (Mod VM IR $''$ : 3.7). *Corresponding mammography* (D): Now reveals an opacity in the upper aspect of the left breast. *Surgical histology*: 1 cm infiltrating ductal carcinoma.

related to early tumor growth [40]. The premise of our review is that this same phenomenon should even be more obvious when using IR as a monitoring tool in patients with tumors associated with extensive vascular activity as seen in LABC.

To evaluate the ability of our high-resolution digital IR imaging station and a modified Ville Marie scoring system to monitor the functional impact of PCT, 20 successive patients with LABC underwent prospective IR imaging, both prior to and after completion of PCT, usually lasting between 3 and 6 months, which was then followed by curative-intent surgery [41]. Ages ranged between 32 and 82 with a mean of 55. Half of the patients were under 50. Patients presented with T2, T3, or inflammatory carcinoma were all free of any distant disease, thus remaining post-PCT surgical candidates. IR was done at the initial clinical evaluation and prior to core biopsy, often ultrasound guided to ensure optimal specimen harvesting,

**TABLE 26.2** Modified Ville Marie Infrared Scoring Scale

IR-1	Absence of any vascular pattern to mild vascular symmetry
IR-2	Symmetrical vascular pattern to moderate vascular asymmetry, particularly if stable or due to known non-cancer causes (eg.: infection, abscess, recent or prior surgery or anatomical asymmetry). Local clinically related vascular asymmetry
IR-3	Regional significant vascular asymmetry (SVA)
IR-4	Extensive SVA, involving at least 1/3 of the breast area
Add the temperature difference ( $\Delta T$ ) in degrees centigrade between the involved area and the corresponding area of the non-involved contralateral breast to calculate final IR score	

which was used to document invasive carcinoma. Both sets of IR images were acquired according to our published protocol [38] using the same integrated infrared station described in our previous section.

We used a modification of the original Ville Marie IR scale (Table 26.2) where IR-1 reflects the absence of any significant vascular pattern to minimal vascular symmetry; IR-2 encompasses symmetrical to moderately asymmetrical vascular patterns, including focal clinically related significant vascular asymmetry; IR-3 implies a regional significant vascular asymmetry (SVA) while an extensive SVA, occupying more than a third of the involved breast, constitutes an IR-4. Mean temperature difference ( $\Delta T$ ) in degrees centigrade between the area of focal, regional or extensive SVA and the corresponding area of the noninvolved breast is then added, resulting in the final IR score.

Conventional clinical response to PCT was done by measuring the maximum tumor diameter in centimeters, both before beginning and after completion of PCT.

Induction PCT in 10 patients, 8 on a clinical trial (NSABP B-27 or B-57) consisted of 4 cycles of adriamycin (A) 60 mg/m<sup>2</sup> and cyclophosphamide (C) 600 mg/m<sup>2</sup>, with or without additional taxotere (T) 100 mg/m<sup>2</sup>, or 6 cycles of AT every 21 days. Eight other patients received AC with additional 5 FU (1000 mg/m<sup>2</sup>) and methotrexate (300 mg/m<sup>2</sup>). Tamoxifen, given to select patients along with the chemotherapy, was used as sole induction therapy in two elderly patients.

Values in both clinical size and IR scoring both before and after chemotherapy were compared using a paired *t*-test.

### 26.2.3 Results

All 20 patients in this series with LABC presented with an abnormal IR image (IR  $\geq$  3). The pre-induction PCT mean IR score was 5.5 (range: 4.4 to 6.9). Infrared imaging revealed a decrease in the IR score in all 20 patients following PCT, ranging from 1 to 5 with a mean of 3.1 (*p* < .05). This decrease following PCT reflected the change in the clinical maximum tumor dimension, which decreased from a mean of 5.2 cm prior to PCT to 2.2 cm (*p* < .05) following PCT in the two-thirds of our series who presented with a measurable tumor. Four of the complete pathological responders in this series saw their IR score revert to normal (<3) following PCT (Figure 26.7) while a fifth had a post-PCT IR score of 3.6. An additional seven patients had a final post-PCT IR score that reflected the final tumor size as measured at surgery (Figure 26.8).

Locally advanced breast cancer is considered an aggressive process that is typically associated with extensive neo-angiogenesis required to sustain rapid and continued tumor growth [27]. Functional IR imaging provided a vivid real-time visual reflection of this invasive process in all our patients. The dramatic IR findings associated with LABC, often occupying more than a third of the breast, are further emphasized by the comparative absence of any significant vascular findings in the uninvolved breast. These images thus provided a new parameter and baseline to complement the traditional structurally based imaging, particularly for the seven patients with clinically nonmeasurable LABC.

The significant reduction in the mean IR score following PCT is primarily an indication of its effect on neo-angiogenesis. While this reduction can sometimes correspond to tumor size, as it did in half of

**FIGURE 26.7** (See color insert.) (a) A 52-year old patient. *Infrared imaging* (A): Extensive vascular asymmetry (SVA) in the right breast with a  $\Delta T$  of 1.2°C (IR-5.2). The patient was started on pre-operative chemotherapy (PCT). *Post-PCT infrared imaging* (B): Resolution of previously noted SVA (IR-2). *Surgical histology*: no residual carcinoma in the resected right breast specimen. (b) A 32-year old patient. *Infrared imaging* (A): Extensive significant vascular asymmetry and tortuous vascular pattern and a  $\Delta T$  of 1.3°C (IR-5.3) in the right breast. *Corresponding mammography* (B): Scattered densities. Patient was started on pre-operative chemotherapy (PCT). *Post-PCT infrared image* (C — left breast; D — right breast): Notable resolution of SVA, with a whole breast  $\Delta T$  of 0.7°C (IR-2). *Surgical histology*: No residual right carcinoma and chemotherapy induced changes.

**FIGURE 26.7** (See color insert.) (c) A 47-year old patient. *Infrared imaging* (A): Extensive significant vascular asymmetry in the inner half of the left breast with a  $\Delta T$  of  $2^{\circ}\text{C}$  (IR-6.0). The patient was started on pre-operative chemotherapy (PCT). *Post-PCT infrared imaging* (B): no residual asymmetry (IR-1). *Surgical histology*: No viable residual carcinoma, with chemotherapy induced dense fibrosis surrounding nonviable tumor cells. (d) A 56-year old patient. *Pre-chemotherapy infrared imaging* (A): Significant vascular asymmetry overlying the central portion of the left breast with a  $\Delta T$  of  $1.35^{\circ}\text{C}$  (IR-4.35). The patient was given pre-operative chemotherapy (PCT). *Post-PCT infrared* (C): mild bilateral vascular symmetry (IR-). *Surgical histology*: no residual tumor.

this series, IR's main contribution concerns functional parameters that can both precede and linger after structural tumor-induced changes occur. Because IR-detected regional angiogenesis responded slightly slower to PCT than did the anatomical parameters in nine patients underscores the fundamental difference between functional imaging such as IR and structural dependent parameters such as clinical tumor dimensions currently used to assess PCT response. IR has the advantage of not being dependent on a minimal tumor size but rather on the tumor's very early necessity to develop an extensive network to survive and proliferate. This would be the basis of IR's ability to sometimes detect tumor growth earlier than can structurally based modalities. The slight discrepancy between the resolving IR score and the anatomical findings in nine of our patients could suggest that this extensive vascular network, most evident in LABC, requires more time to dismantle in some patients. It could reflect the variable volume of angiogenesis, the inability of PCT to affect it, and thus possibly constitute a prognostic factor. This feature could also result from a deficiency in our proposed scoring scale.

**FIGURE 26.7** (See color insert.) (e) A 54-year old patient. *Infrared image (A)*: extensive significant vascular asymmetry right breast with a  $rT$  of  $2.8^{\circ}\text{C}$  (IR-6.8). Received pre-operative chemotherapy (PCT). *Post-PCT infrared (B)*: Mild local residual vascular asymmetry with a  $rT$  of  $1.65^{\circ}\text{C}$  (IR-3.65). *Surgical pathology*: No residual viable carcinoma.

**FIGURE 26.8** (See color insert.) Pre-PCT and Post-PCT IR Score and histological maximum tumor dimension (MTD).

Further study and follow-up are needed to better evaluate whether the sequential utilization of this practical imaging modality can provide additional pertinent information regarding the efficacy of our current and new therapeutic strategies, particularly in view of the increasing number with anti-angiogenesis properties, and whether lingering IR-reflected neo-angiogenesis following PCT ultimately reflects on prognosis.

**FIGURE 26.9** (See color insert.) (a) A stable vascular distribution in the lower inner quadrant of the left breast over a 12-month period. *Infrared imaging* of the breast usually remains remarkably stable in the absence of any on going developing significant pathology. It is important in grading these images to determine if the findings are to be considered evolving and important or stable and possibly relating to the patient’s vascular anatomy. (b) An identical vascular distribution of the left breast over a 12-month period. (c) A stable vascular distribution in both breasts over a 12-month period.

### 26.3 Future Considerations Concerning Infrared Imaging

Mammography, our current standard first-line imaging modality only reflects an abnormality that could then prompt the alert clinician to intervene rather than to observe. This decision is crucial since it is at this first level that sensitivity and specificity are most vulnerable. There is a clear consensus that we have not yet developed the ideal breast cancer imaging technique and this is reflected in the flurry of

**FIGURE 26.10** (See color insert.) (a) A 50-year old patient. *Infrared imaging* (A): Significant vascular asymmetry and a  $\Delta T$  of 3.4°C (IR-5) in the right breast. *Corresponding mammography* (B): Increased density and microcalcifications in the right breast. *Surgical histology*: extensive right multifocal infiltrating ductal carcinoma requiring a total mastectomy. (b) A 50-year old patient. *Infrared imaging* (A): Significant vascular asymmetry with a near global  $\Delta T$  of 2.35°C in the left breast (IR-5). *Mammography* (not available) diffuse density. *Surgical histology*: Left multi-focal infiltrating ductal carcinoma requiring a total mastectomy.

new modalities that have recently appeared. While progress in imaging and better training have resulted in the gradual decrease in the average size of breast tumors over the previous decade, the continued search for improved imaging must continue to further reduce the false negative rate and promote earlier detection.

Digital mammography is already recognized as a major imaging facilitator with the capability to do tomosynthesis and subtraction, along with state of the art 3D and 4D ultrasound. However, there is now new emphasis on developing functional imaging that can exploit early vascular and metabolic changes associated with tumor initiation that often predate morphological changes that most of our current structural imaging modalities still depend on; thus, the enthusiasm in the development of sestamibi scanning, doppler ultrasound, and MRI of the breast [42,43]. Unfortunately, as promising as these modalities are, they are often too cumbersome, costly, inaccessible, or require intravenous access to be used as first-line detection modalities alongside clinical exam and mammography.

**FIGURE 26.11** (See color insert.) (a) Four years post right partial mastectomy, the patient is recurrence free. Current *Infrared imaging* (A): shows no activity and *Mammography* (B): shows scar tissue. (b) *Infrared image*, 5 years following a left partial mastectomy and radiotherapy for carcinoma revealing slight asymmetry of volume, but no abnormal vascular abnormality and resolution of radiation-induced changes. The patient is disease free.

On the other hand, integrating IR imaging, a safe and practical modality into the first-line strategy, can increase the sensitivity at this crucial stage by also providing an early warning signal of an abnormality that in some cases is not evident in the other components. Combining IR imaging and mammography in an “IR-Assisted Mammography Strategy” is particularly appealing in the current era of increased emphasis on detection by imaging with less reliance on palpation as tumor size further decreases.

Intercenter standardization of a protocol concerning patient preparation, temperature controlled environment, digital image production, enhanced grading, and archiving, as well as data collection and sharing are all important factors that are beginning to be addressed. New technology could permit real-time image acquisition that could be submitted to computerized assisted image reading which will further enhance the physician’s ability to detect subtle abnormalities.

Physician training is an essential quality control component for this imaging modality to contribute its full potential. A thorough knowledge of all aspects of benign and malignant breast pathology and concomitant access to prior IR imaging that should normally remain stable (Figure 26.9) are all contributory features. This modality needs to benefit from the same quality control previously applied to mammography and should not, at this time, be used as stand alone. It should benefit from the same

interaction between clinical knowledge and other imaging tools as is the case in current breast cancer detection in the clinical environment. This is especially important since there are no current IR regulations, as it poses no health threat and does not use radiation, and could thus fall victim to untrained personnel who could misuse it on unsuspecting patients as was previously the case.

Its future promise, however, resides primarily in its ability to qualify and quantify vascular and metabolic changes related to early tumor genesis. The proposals that a higher temperature difference ( $\Delta T$ ) and increased vascular asymmetry are prognostic factors of tumor aggressivity need to be validated by further research (Figure 26.10). The same applies to the probability that the reduction of IR changes seen with pre-operative chemohormonotherapy reflect reduction in neo-angiogenesis and thus treatment efficacy. These remain, at the very least, extremely interesting and promising areas for future research, particularly

**FIGURE 26.12** (See color insert.) A 52-year old patient, 5 years following right partial mastectomy, radiation, and chemotherapy for right breast cancer. Recent follow-up Infrared Imaging (A) now reveals significant vascular asymmetry (SVA) in the right breast with a  $\Delta T$  of 1.5°C in the area of the previous surgery (IR-4). *Corresponding mammography* (B): Density and scar issue vs. possible recurrence. *Surgical histology*: 4 cm, recurrent right carcinoma in the area of the previous resection.

**FIGURE 26.13** (See color insert.) (a) A 45-year old patient with small nodular process just inferior and medial to the left nipple areolar complex. *Infrared imaging* (A), without digital enhancement, was carried out and circles were placed on the nipple area rather than just below and medial to it. The nonenhanced IR image was thus initially misinterpreted as normal with a  $\Delta T$  of 0.25°C. The same image was recalled and *repeated* (B), now with appropriate digital enhancement and once again, documented the presence of increased vascular activity just inferior and medial to the left nipple areolar complex with a  $\Delta T$  of 1.15°C (IR-4.15). A 1.5 cm. cancer was found just below the left nipple.

**FIGURE 26.13** (Continued.) (See color insert.) (b) A 37-year old patient with lump in the upper inner quadrant of the left breast. Mammography confirms spiculated mass. *Infrared imaging* (A): Reported as “normal.” Infrared imaging was repeated after appropriate *digital adjustment* (B): Now reveals obvious significant vascular asymmetry in the same area and a  $\Delta T$  of 1.75°C (Ir-4) (mod IR-4.75). Using a different IR camera on the *same patient* (C) confirms same finding. *Surgical histology*: 1.5 cm infiltrating ductal CA.

in view of the current interest in new angiogenesis-related therapeutic strategies. Its contribution to monitoring post-operative patients (Figure 26.11) which is problematic with both mammography and ultrasound [44] and its ability to recognize recurrent cancer (Figure 26.12) are other areas for further clinical trials. Adequate physician training and strict attention to image acquisition are essential to avoid false negative interpretation (Figure 26.13).

As is the case for all current imaging modalities, the fact that this modality does not detect all tumors should not detract from its contribution as a functional adjuvant addition to our current first-line imaging strategy that is still based essentially on mammography alone, a structural modality that has reached its full potential. There is already sufficient data regarding IR’s sensitivity and specificity that has been more recently validated and on going data collection will be important to justify its continued use in the ever evolving breast imaging field. Infrared imaging will soon replace current imaging modalities as an alternative, which would be both uninvasive and yet more informative first-line tool. In the meantime, to ignore its contribution to the very complex process of promoting earlier breast cancer detection could be questioned. A good first-line imaging modality must be safe, convenient, and able to help detect primarily the more aggressive tumors where early intervention can have a greater impact on survival.

One of the popular methods for breast cancer detection is to make comparisons between contralateral images. When the images are relatively symmetrical, small asymmetries may indicate a suspicious region. In thermal infrared (IR) imaging, asymmetry analysis normally needs human intervention because of the difficulties in automatic segmentation. In order to provide a more objective diagnostic result, we describe an automatic approach to asymmetry analysis in thermograms. It includes automatic segmentation and supervised pattern classification. Experiments have been conducted based on images provided by Elliott Mastology Center (Inframetrics 600M camera) and Bioyear, Inc. (Microbolometer uncooled camera).

### 27.1 Introduction

---

The application of IR imaging in breast cancer study starts as early as 1961 when Williams and Handley first published their results in the *Lancet* [1]. However, the premature use of the technology and its poorly controlled introduction into breast cancer detection in the 1970s have led to its early demise [2]. IR-based diagnosis was criticized as generating a higher false-positive rate than mammography, and thus was not recommended as a standard modality for breast cancer detection. Therefore, despite its deployment in

many areas of industry and military, IR usage in medicine has declined [3]. Three decades later, several papers and studies have been published to reappraise the use of IR in medicine [2,3] for the following three reasons (1) We have greatly improved IR technology. New generations of IR cameras have been developed with much enhanced accuracy; (2) We have much better capabilities in image processing. Advanced techniques including image enhancement, restoration, and segmentation have been effectively used in processing IR images; and (3) We have a deeper understanding of the patho-physiology of heat generation.

The main objective of this work is to evaluate the viability of IR imaging as a noninvasive imaging modality for early detection of breast cancer so that it can be performed both on the symptomatic and the asymptomatic patient and can thus be used as a complement to traditional mammography. This report summarizes how the identification of the asymmetry can be automated using image segmentation, feature extraction, and pattern recognition techniques. We investigate different features that contribute the most toward the detection of asymmetry. This kind of approach helps reduce the false-positive rate of the diagnosis and increase chances of disease cure and survival.

### **27.1.1 Measuring the Temperature of Human Body**

Temperature is a long established indicator of health. The Greek physician, Hippocrates, wrote in 400 B.C. “In whatever part of the body excess of heat or cold is felt, the disease is there to be discovered” [4]. The ancient Greeks immersed the body in wet mud and the area that dried more quickly, indicating a warmer region, was considered the diseased tissue. The use of hands to measure the heat emanating from the body remained well into the 16th and the 17th centuries. It wasn’t until Galileo, who made a thermoscope from a glass tube, that some form of temperature sensing device was developed, but it did not have a scale. It is Fahrenheit and later Celsius who have fixed the temperature scale and proposed the present day clinical thermometer. The use of liquid crystals is another method of displaying skin temperature. Cholesteric esters can have the property of changing colors with temperature and this was established by Lehmann in 1877. It was involved in use of elaborative panels that encapsulated the crystals and were applied to the surface of the skin, but due to large area of contact, they affected the temperature of the skin. All the methods discussed above are contact based.

Major advances over the past 30 years have been with IR thermal imaging. The astronomer, Sir William Herschel, in Bath, England discovered the existence of IR radiation by trying to measure the heat of the separate colors of the rainbow spectrum cast on a table in the darkened room. He found that the highest temperature was found beyond the red end of the spectrum. He reported this to the Royal society as Dark Heat in 1800, which eventually has been turned the IR portion of the spectrum. IR radiation occupies the region between visible and microwaves. All objects in the universe emit radiations in the IR region of the spectra as a function of their temperature. As an object gets hotter, it gives off more intense IR radiation, and it radiates at a shorter wavelength [3]. At moderate temperatures (above 200°F), the intensity of the radiation gets high enough that the human body can detect that radiation as heat. At sufficiently high temperatures (above 1200°F), the intensity gets high enough and the wavelength gets short enough that the radiation crosses over the threshold to the red end of the visible light spectrum. The human eye cannot detect IR rays, but they can be detected by using the thermal IR cameras and detectors.

### **27.1.2 Metabolic Activity of Human Body and Cancer Cells**

Metabolic process in a cell can be briefly defined as the sum total of all the enzymatic reactions occurring in the cell. It can be further elaborated as a highly coordinated, purposeful activity in which many sets of interrelated multienzyme systems participate, exchanging both matter and energy between the cell and its environment. Metabolism has four specific functions (1) To obtain chemical energy from the fuel molecules; (2) To convert exogenous nutrients into the building blocks or precursor of macromolecular cell components; (3) To assemble such building blocks into proteins, nucleic acids, lipids, and

other cell components; and (4) To form and degrade biomolecules required in specialized functions of the cell.

Metabolism can be divided into two major phases, Catabolism and Anabolism. Catabolism is the degradative phase of metabolism in which relatively large and complex nutrient molecules (carbohydrates, lipids, and proteins) are degraded to yield smaller, simpler molecules such as lactic acid, acetic acid,  $\text{CO}_2$ , ammonia, or urea. Catabolism is accompanied by conservation of some of the energy of the nutrient in the form of phosphate bond energy of adenosine triphosphate (ATP). Conversely, anabolism is the building up phase of metabolism, the enzymatic biosynthesis of such molecular components of cells as the nucleic acids, proteins, lipids, and carbohydrates from their simple building block precursors. Biosynthesis of organic molecules from simple precursors requires input of chemical energy, which is furnished by ATP generated during catabolism. Each of these pathways is promoted by a sequence of specific enzymes catalyzing consecutive reactions. The energy produced by the metabolic pathways is utilized by the cell for its division. Cells undergo mitotic cell division, a process in which a single cell divides into many cells and forms tissues, leading further into the development and growth of the multicellular organs. When cells divide, each resultant part is a complete relatively small cell. Immediately after division the newly formed cells grow rapidly soon reaching the size of the original cell. In humans, growth occurs through mitotic cell division with subsequent enlargement and differentiation of the reproduced cells into organs. Cancer cells also grow similarly but lose the ability to differentiate into organs. So, a cancer may be defined as an actively dividing undifferentiated mass of cells called the “tumor.”

Cancer cells result from permanent genetic change in a normal cell triggered by some external physical agents such as chemical agents, x-rays, UV rays, etc. They tend to grow aggressively and do not obey normal pattern of tissue formation. Cancer cells have a distinctive type of metabolism. Although they possess all the enzymes required for most of the central pathways of metabolism, cancer cells of nearly all types show an anomaly in the glucose degradation pathway (viz. Glycolysis). The rate of oxygen consumption is somewhat below the values given by normal cells. However the malignant cells tend to utilize anywhere from 5 to 10 times as much glucose as normal tissue and convert most of it into lactate instead of pyruvate (lactate is a low energy compound whereas pyruvate is a high energy compound). The net effect is that in addition to the generation of ATP in mitochondria from respiration, there is a very large formation of ATP in extramitochondrial compartment from glycolysis. The most important effect of this metabolic imbalance in cancer cells is the utilization of a large amount of blood glucose and release of large amounts of lactate into blood. The lactate so formed is recycled in the liver to produce blood glucose again. Since the formation of blood glucose by the liver requires 6 molecules of ATP whereas breakdown of glucose to lactate produces only 2 ATP molecules, the cancer cells are looked upon as metabolic parasites dependent on the liver for a substantial part of their energy. Large masses of cancer cells thus can be a considerable metabolic drain on the host organism. In addition to this, the high metabolic rate of cancer cells causes an increase in local temperature as compared to normal cells. Local metabolic activity ceases when blood supply is stopped since glycolysis is an oxygen dependent pathway and oxygen is transported to the tissues by the hemoglobin present in the blood; thus, blood supply to these cells is important for them to proliferate. The growth of a solid tumor is limited by the blood supply. If it were not invaded by capillaries a tumor would be dependent on the diffusion of nutrients from its surroundings and could not enlarge beyond a diameter of a few millimeters. Thus, in order to grow further the tumor cells stimulate the blood vessels to form a capillary network that invades the tumor mass. This phenomenon is popularly called “angiogenesis,” which is a process of vascularization of a tissue involving the development of new capillary blood vessels.

Vascularization is a growth of blood vessels into a tissue with the result that the oxygen and nutrient supply is improved. Vascularization of tumors is usually a prelude to more rapid growth and often to metastasis (advanced stage of cancer). Vascularization seems to be triggered by angiogenesis factors that stimulate endothelial cell proliferation and migration. In the context of this paper the high metabolic rate in the cancer cells and the high density of packaging makes them a key source of heat concentration (since the heat dissipation is low) thus enabling thermal IR imaging as a viable technique to visualize the abnormality.

### 27.1.3 Early Detection of Breast Cancer

There is a crucial need for early breast cancer detection. Research has shown that if detected earlier (tumor size less than 10 mm), the breast cancer patient has an 85% chance of cure as opposed to 10% if the cancer is detected late [5].

Different kinds of diagnostic imaging techniques exist in the field of breast cancer detection. The most popularly used method presently is x-ray mammography. The drawback of this technique is that it is invasive and experts believe that electromagnetic radiation can also be a triggering factor for cancerous growth. Because of this, periodic inspection might have a negative effect on the patient's health. Research shows that the mammogram sensitivity is higher for older women (age group 60 to 69 years) at 85% compared with younger women (<50 years) at 64% [5]. A new study in a British medical journal (The LANCET [6]) has asserted that there is no reliable evidence that screening with mammography for breast cancer reduces mortality. They show that screening actually leads to more aggressive treatment, increasing the number of mastectomies by about 20%, and the number of mastectomies and tumorectomies by about 30%.

In contrast to this IR imaging uses a noninvasive imaging technique as the diagnostic tool. The main source of IR rays is heat emitted from different bodies whose temperature is above absolute zero. Thus a thermogram of a patient provides the heat distribution in the body. The cancerous cells, due to high metabolic rates and angiogenesis, are at a higher temperature than the normal cells around it. Thus the cancer cells can be imaged as hotspots in the IR images. The thermogram provides more dynamic information of the tumor since the tumor can be small in size but can be fast growing making it appear as a high temperature spot in the thermogram [7,8]. However, this is not the case in mammography, in which unless the tumor is beyond certain size, it cannot be imaged as x-rays essentially pass through it unaffected. This qualifies IR imaging as an effective diagnostic tool for early detection of breast cancer. Keyserlingk et al. [2] reported that the average tumor size undetected by thermal imaging is 1.28 cm and 1.66 cm by mammography. It is also reported that thermography can provide results that can be correct even 8 to 10 years before mammography can detect a mass in the patient's body [9,10].

## 27.2 Asymmetric Analysis in Breast Cancer Detection

---

Radiologists routinely make comparisons between contralateral images. When the images are relatively symmetrical, small asymmetries may indicate a suspicious region. This is the underlying philosophy in the use of asymmetry analysis for mass detection in breast cancer study [11]. Unfortunately, due to various reasons like fatigue, carelessness, or simply because of the limitation of human visual system, these small asymmetries might not be easy to detect. Therefore, it is important to design an automatic approach to eliminate human factors.

There have been a few papers addressing techniques for asymmetry analysis of mammograms [11–16]. Head et al. [17,18] recently analyzed the asymmetric abnormalities in infrared images. In their approach, the thermograms are segmented first by an operator. Then breast quadrants are derived automatically based on unique point of reference, that is, the chin, the lowest, rightmost, and leftmost points of the breast.

This chapter describes an automatic approach to asymmetry analysis in thermograms. It includes automatic segmentation and pattern classification. Hough transform is used to extract the four feature curves that can uniquely segment the left and right breasts. The feature curves include the left and the right body boundary curves, and the two parabolic curves indicating the lower boundaries of the breasts. Upon segmentation, different pattern recognition techniques are applied to identify the asymmetry.

Both segmentation and classification results are shown on images provided by Elliott Mastology Center (Inframetrics 600M camera) and Biyear, Inc. (Microbolometer uncooled camera).

### 27.2.1 Automatic Segmentation

There are several ways to perform segmentation, including *threshold-based* techniques, *edge-based* techniques, and *region-based* techniques. Threshold-based techniques assign pixels above (or below) a specified

threshold to be in the same region. Edge-based techniques assume that the boundary formed by adjacent regions (or segments) has high edge strength. Through edge detection, we can identify the boundary that surrounds a region. Region-based methods start with elemental regions and split or merge them [19].

### 27.2.1.1 Edge Image Generation

In this research work, we choose to use the edge-based segmentation technique as we have identified four dominant curves in the edge image, which we call “feature curves,” including the left and right body boundaries, and the two lower boundaries of the breasts (Figure 27.3) or the two shadow boundaries that are below the breasts (Figure 27.2) whichever is stronger.

Edges are areas in the image where the brightness changes suddenly. One way to find edges is to calculate the amplitude of the first derivative (Equation 27.1) that generates the so-called gradient magnitude image where  $\partial f/\partial x$  is the derivative of the image  $f$  along the  $x$  direction, and  $\partial f/\partial y$  is the derivative along the  $y$  direction (the  $x$  and  $y$  directions are orthogonal to each other) and to threshold the amplitude image.

$$\text{Gradient magnitude} = \sqrt{\left(\frac{\partial f}{\partial x}\right)^2 + \left(\frac{\partial f}{\partial y}\right)^2} \quad (27.1)$$

Another way is to calculate the second derivative and to locate the zero-crossing points, as the second derivative at edge pixels would appear as a point where the derivatives of its left and right pixels change signs.

Although effective, both derivative images are very sensitive to noise. In order to eliminate or reduce the effect of noise, a Gaussian smoothing low-pass filter is applied before taking the derivatives. The smoothing process, on the other hand, also results in thicker edges. The Canny edge detector [20] solves this problem by taking two extra steps, the *nonmaximum suppression* (NMS) step and the *hysteresis thresholding* step, in order to locate the true edge pixels (only one pixel wide along the gradient direction).

For each edge pixel in the gradient magnitude image, the NMS step looks one pixel in the direction of the gradient, and another pixel in the reverse direction. If the magnitude of the current pixel is not the maximum of the three, then this pixel is not a true edge pixel. NMS helps locate the true edge pixels properly. However, the new edges still suffer from extra edge points problem due to noise and missing edge points.

The hysteresis thresholding improves the quality of edge image by using a dual-threshold approach, in which two thresholds,  $\tau_1$  and  $\tau_2$  ( $\tau_2$  is significantly larger than  $\tau_1$ ), are applied on the NMS-processed edge image to produce two binary edge images, denoted as  $T_1$  and  $T_2$ , respectively. Since  $T_1$  was created using a lower threshold, it will contain more extra edge pixels than  $T_2$ . Edge pixels in  $T_2$  are therefore considered to be parts of true edges. When some discontinuities in edges occur in the  $T_2$  image, the pixels at the same location of the  $T_1$  image is looked up that could be continuations of the edge. If such pixels are found, they are included in the true edge image. This process continues until the continuation of pixels in  $T_1$  connects with an edge pixel in  $T_2$  or no connected  $T_1$  points are found. (See Figure 27.2 and Figure 27.3 for examples of the edge image derived from Canny edge detector.)

### 27.2.1.2 Hough Transform for Edge Linking

From Figure 27.2 and Figure 27.3, we find that the edge images still cannot be used directly for segmentation as the edge detector picks up all the intensity changes, which would complicate the segmentation. On the other hand, many edges show gaps among edge pixels that would result in segments that are not closed. We have identified four feature boundaries that could enclose the breast. The body boundaries are easy to detect. Difficulties lie in the detection of the lower boundaries of the breasts or the shadow. We observe that the breast boundaries are generally parabolic in shape. Therefore, the Hough transform [21] is used to detect the parabola.

FIGURE 27.1 Illustration of the Hough transform. (a) The original image domain and (b) The parametric domain.

The Hough transform is one type of parametric transforms, in which the object in an image is expressed as a mathematical function of some parameters and the object can be represented in another transformation domain by these parameters. Take a straight edge in an image as an example, in the original image representation domain (or the  $x - y$  domain), we can use  $y = ax + b$  to describe this edge with a slope of  $a$  and an intercept of  $b$ , as shown in Figure 27.1a. In order to derive the two parameters,  $a$  and  $b$ , we can convert the problem to a parametric domain (or the  $a - b$  domain) from the original  $x - y$  space, and treat  $x$  and  $y$  as parameters. We find that for each point  $(x, y)$  on the edge, there are infinite number of possible corresponding  $(a, b)$ s and they form a line in the  $a - b$  space,  $b = xa + y$ . We can imagine that for all the points on the edge, if each of which corresponds to a straight line in the  $a - b$  space, then in theory, these lines must intersect at one and only one point (Figure 27.1b), which indicates the true slope and intercept of the edge.

Similarly, the problem of deriving the parameters that describe the parabola can be formulated in a three-dimensional (3D) parametric space of  $x_0 - y_0 - p$  as there are three unknown parameters:

$$y - y_0 = p(x - x_0)^2 \tag{27.2}$$

Each point on the parabola in the  $x - y$  space corresponds to a parabola in the  $x_0 - y_0 - p$  space. All the points on the parabola in the  $x - y$  space intersect at one point in the  $x_0 - y_0 - p$  space. In order to locate this intersection point in the parametric space, the idea of *accumulator array* is used in which the number of times that a certain pixel in the parametric space is “hit” by a transformed curve (line, parabola, etc.) is treated as the intensity of the pixel. Therefore, the value of the parameters can be derived based on the coordinates of the brightest pixel in the parametric space. The readers are referred to Reference 19 for details on how to implement this accumulator array.

The coordinates of the two brightest spot in the parametric space are used to describe the parabolic functions that form the lower boundaries of the breasts, as shown in Figure 27.2 and Figure 27.3.

**27.2.1.3 Segmentation Based on Feature Boundaries**

Segmentation is based on three key points, the two armpits ( $P_L, P_R$ ) derived from the left and right body boundaries by picking up the point where the largest curvature occurs and the intersection ( $O$ ) of the two parabolic curves derived from the lower boundaries of the breasts/shadow of the breasts. The vertical line that goes through point  $O$  and is perpendicular to line  $P_L P_R$  is the one used to separate the left and right breasts.

**27.2.1.4 Experimental Results**

The first set of testing images are obtained using the Inframetrics 600M camera, with a thermal sensitivity of  $0.05^\circ\text{K}$ . The images are collected at Elliott Mastology Center. Results from two testing images ( $lr, nb$ ) are shown in Figure 27.2, that includes the intermediate results from edge detection, feature curve

FIGURE 27.2 Segmentation results of two images. Left: results from *lr*. Right: results from *nb*. From top to bottom: original image, edge image, four feature curves, and segments (©2005 IEEE).

FIGURE 27.3 Hough transform based image segmentation. Top: image of a patient with cancer. Bottom: image of a patient without cancer. From left to right: the original TIR image, the edge image using Canny edge detector, and the segmentation based on Hough transform (©2005 IEEE).

extraction, and segmentation. From the figure, we can see that Hough transform can derive the parabola at the accurate location.

Another set of images are obtained using Microbolometer uncooled camera, with a thermal sensitivity of  $0.05^{\circ}\text{K}$ . Some examples of the segmented images are shown in Figure 27.3.

**FIGURE 27.4** The left figure show the intensity distribution of a cancerous image and the right figure shows the same for a noncancerous image. The cancerous image is more asymmetrical than the noncancerous one.

Figure 27.4 shows the 3D histogram of the thermal distribution described in the intensity component of the cancerous (*ca*) and noncancerous (*nm*) images. From the graphs, we observe that the *ca* image is more asymmetrical than the *nm* image.

### 27.2.2 Asymmetry Identification by Unsupervised Learning

Pixel values in a thermogram represent the thermal radiation resulting from the heat emanating from the human body. Different tissues, organs, and vessels have different amount of radiation. Therefore, by observing the heat pattern, or in another word, the pattern of the pixel value, we should be able to discover the abnormalities if there are any.

Usually, in pattern classification algorithms, a set of training data are given to derive the decision rule. All the samples in the training set have been correctly classified. The decision rule is then applied to the testing data set where samples have not been classified yet. This classification technique is also called supervised learning. In unsupervised learning, however, data sets are not divided into training sets or testing sets. No a priori knowledge is known about which class each sample belongs to.

In asymmetry analysis, none of the pixels in the segment knows its class in advance, thus there will be no training set or testing set. Therefore, this is an unsupervised learning problem. We use *k*-means algorithm to do the initial clustering. *k*-means algorithm is described as follows:

1. Begin with an arbitrary set of cluster centers and assign samples to nearest clusters
2. Compute the sample mean of each cluster
3. Reassign each sample to the cluster with the nearest mean
4. If the classification of all samples has not changed, then stop, else go to step 2

After each sample is relabeled to a certain cluster, the cluster mean can then be calculated. The segmented image can also be displayed in labeled format. From the difference of mean distribution, we can tell if there is any asymmetric abnormalities.

Figure 27.5 provides the histogram of pixel value from each segment that generated in Figure 27.2 with 10-bin setup. We can tell just from the shape of the histogram that *lr* is more asymmetric than *nb*. However, the histogram only reveals global information. Figure 27.6 displays the classification results for each segment in its labeled format. Here, we choose to use four clusters. The figure also shows the mean difference of each cluster in each segmented image. From Figure 27.6, we can clearly see the much bigger difference shown in the mean distribution or image *lr*, which can also be observed from the labeled image.

FIGURE 27.5 Histogram of the left and right segments. Top: results from *lr*. Bottom: results from *nb*. From left to right: the segments, histogram of the left segment, histogram of the right segment (©2005 IEEE).

**FIGURE 27.6** Labeled image and the profile of mean for each cluster. (a) Results from *lr*, (b) labeled image, (c) results from *nb*, and (d) average pixel value profile of each cluster (©2005 IEEE).

### 27.2.3 Asymmetry Identification Using Supervised Learning Based on Feature Extraction

Feature extraction is performed on the segmented images. The aim of this research is to identify the effectiveness of the features in contributing toward the asymmetry analysis.

As discussed earlier, TIR imaging is a functional imaging technique representing thermal information as a function of intensity. The TIR image is a pseudo-colored image with different colors assigned to different temperature ranges.

The distribution of different intensities can now be quantified by calculating some high-order statistics as feature elements. We design the following features to form the feature space:

- *Moments of the intensity image*: The intensity component of the image directly corresponds to the thermal energy distribution in the respective areas. The histogram describing the intensity distributions essentially describes the texture of the image. The moments of the histogram give statistical information about the texture of the image. Figure 27.5 shows the intensity distribution of images of a cancerous patient and non-cancerous patient. The four moments, mean, variance, skewness, and kurtosis are taken as

$$\text{Mean } \mu = \frac{1}{N} \sum_{j=1}^N p_j \tag{27.3}$$

$$\text{Variance } \sigma^2 = \frac{1}{N-1} \sum_{j=1}^N (p_j - \mu)^2 \tag{27.4}$$

$$\text{Skewness} = \frac{1}{N} \sum_{j=1}^N \left[ \frac{p_j - \mu}{\sigma} \right]^3 \tag{27.5}$$

$$\text{Kurtosis} = \frac{1}{N} \sum_{j=1}^N \left( \frac{p_j - \mu}{\sigma} \right)^4 \tag{27.6}$$

where  $p_j$  is the probability density of the  $j$ th bin in the histogram, and  $N$  is the total number of bins.

- *The peak pixel intensity of the correlated image*: The correlated image between the left and right (reflected) breasts is also a good indication of asymmetry. We use the peak intensity of the correlated image as a feature element since the higher the correlation value, the more symmetric the two breast segments.
- *Entropy*: Entropy measures the uncertainty of the information contained in the segmented images. The more equal the intensity distribution, the less information. Therefore, the segment with hot spots should have a lower Entropy.

$$\text{Entropy } H(X) = - \sum_{j=1}^N p_j \log p_j \tag{27.7}$$

- *Joint Entropy*: The higher the joint entropy between the left and right breast segments, the more symmetric they are supposedly to be, and the less possible of the existence of tumor.

$$\text{Joint Entropy } H(X, Y) = \sum_{i=1}^{N_X} \sum_{j=1}^{N_Y} p_{ij} \log(p_{ij}) \tag{27.8}$$

**TABLE 27.1** Moments of the Histogram

Moments	Cancerous		Noncancerous	
	Left	Right	Left	Right
Mean	0.0010	0.0008	0.0012	0.0010
Variance ( $10^{-6}$ )	2.0808	1.1487	3.3771	2.7640
Skewness ( $10^{-6}$ )	2.6821	1.1507	4.8489	4.5321
Kurtosis ( $10^{-8}$ )	1.0481	0.3459	2.1655	2.3641

**TABLE 27.2** Entropy and Correlation Values

Feature	Cancerous	Noncancerous
Correlation	$\times 10^8$	$2.35719 \times 10^8$
Joint Entropy	9.0100	17.5136
Entropy		
Left	1.52956	1.70684
Right	1.3033	1.4428

where  $p_{ij}$  is the joint probability density,  $N_X$  and  $N_Y$  are the number of bins of the intensity histogram of images  $X$  and  $Y$  respectively.

From the set of features derived from the testing images, the existence of asymmetry is decided by calculating the ratio of the feature from the left segment to the feature from the right segment. The closer the value to one, the more correlated the features or the less asymmetric the segments. Classic pattern classification techniques like the maximum posterior probability and the kNN classification [22] can be used for the automatic classification of the images. Table 27.1 describes the typical moments for the cancerous and noncancerous images.

The typical values of the cancerous images and noncancerous images are tabulated in Table 27.2. The asymmetry can be clearly stated with a close observation of the given feature values. We used 6 normal patient thermograms and 18 cancer patient thermograms. With a larger database, a training feature set can be derived and supervised learning algorithms like discriminant function or kNN classification can be implemented for a fast, effective, and automated classification.

Figure 27.7 evaluates the effectiveness of the features used. The first data point along the  $x$ -axis indicates *entropy*, the second to the fifth points indicate the four statistical moments (*means, variance, skewness, and kurtosis*). The  $y$ -axis shows the *closeness* metric we defined as

$$\text{Bilateral ratio closeness to 1} = \left| \frac{\text{feature value from left segment}}{\text{feature value from right segment}} - 1 \right| \tag{27.9}$$

From the figure, we observe that the high-order statistics are the most effective features to measure the asymmetry, while low-order statistics (*mean*) and *entropy* do not assist asymmetry detection.

### 27.3 Conclusions

This paper develops a computer-aided approach for automating asymmetry analysis of thermograms. This kind of approach will help the diagnostics as a useful second opinion. The use of TIR images for breast cancer detection and the advantages of thermograms over traditional mammograms are studied. From the experimental results, it can be observed that the Hough transform can be effectively used for breast segmentation. We propose two pattern classification algorithms, the unsupervised learning

**FIGURE 27.7** Performance evaluation of different feature elements. Solid line: non-cancerous image; Dash line: cancerous image. The five data points along the x-axis indicate (from left to right): entropy, mean, variance, skewness, and kurtosis (©2005 IEEE).

using k-means and the supervised learning using kNN based on feature extraction. Experimental results show that feature extraction is a valuable approach to extract the signatures of asymmetry, especially the joint entropy. With a larger database, supervised pattern classification techniques can be used to attain more accurate classification. These kind of diagnostic aids, especially in a disease like breast cancer where the reason for the occurrence is not totally known, will reduce the false-positive diagnosis rate and increase the survival rate among the patients since the early diagnosis of the disease is more curable than in a later stage.

Thermal imaging can be useful as an early diagnostic technique that can detect many diseases, such as for example, breast cancer, malignant tumors, etc. There are many different methods that describe image features. A large group of methods is based on statistical parameters calculations. Parameters like mean value, standard deviation, skewness, kurtosis, etc. can be used to compare thermal images. We consider both the first and second order statistical parameters [1,2]. The first order statistical parameters methods use image's histogram (Figure 28.1) to compute signatures, while the second order statistical parameters are defined for so-called co-occurrence matrix of the image [2,11].

In medical applications, one of the principal features of the thermal image is its symmetry of temperature patterns. Thermal images are usually asymmetrical in pathological cases. Any significant asymmetry can indicate a physiologic abnormality (Figure 28.2). This may be pathological (including cancer, fibrocystic disease, an infection, or a vascular disease) or it might indicate an anatomical variant [4–6].

The next group of methods is based on image transformations, such as linear filtering, Fourier or wavelet analysis. All these methods allow to regenerate an image which is processed or converted, and signatures are defined in different domain, for example, frequency or scale domains. Well-known Karhunen-Loeve transform is implemented in form of principle component analysis (PCA). PCA is a technique that is usually used for reducing the dimensionality of multivariate data, preserving most of the variance [7–9].

Thermal image classification is a powerful tool for many medical diagnostic protocols, for example, during breast cancer screening [3,10,11]. Figure 28.3 and Figure 28.4 show thermal images of a healthy breast and that with malignant tumor, respectively. Among the variety of different image features, statistical thermal signatures (first and second order) have been already effectively used for classification of images represented by raw data [1,2,10,12]. In another approach, the features obtained from wavelet transformation can also be used for successful classification.

FIGURE 28.3 (See color insert.) Thermal image of the healthy breast.

**FIGURE 28.4** (See color insert.) Thermal image of the breast with malignant tumor (left side).

It is possible to define many features for an image, and obviously, the selection and reduction are needed. Two approaches are applied, based on Fischer coefficient as well as by using minimization of classification error probability (POE) and average correlation coefficients (ACC), calculated for chosen features [13]. It can reduce the number of features to a few ones. Features preprocessing which generates new parameters after linear or nonlinear transformations can be the next step in the procedure. It allows to get less correlated and of the lower order data. Two approaches are used, that is, PCA and linear discriminant analysis (LDA) [1,3,8]. Finally, classification can be performed using different artificial neural network (ANN), with or without additional hidden layers, and with different number of neurons. Alternatively, nearest neighbor classification (NNC) can also be employed for such image processing.

## 28.1 Histogram-Based First Order Thermal Signatures

An image is assumed to be a rectangular matrix of discretised data (pixels)  $\text{pix}[m, n]$ , where  $m = 0, 1, \dots, M$ ,  $n = 0, 1, \dots, N$ . Each pixel takes a value from the range  $i \in \langle 0, L - 1 \rangle$ . The histogram describes the frequency of existence of pixels of the same intensity in whole image or in the region of interest (ROI). Formally, the histogram represents the distribution of the probability function of the existence of the given intensity in an image and it is expressed using Kronecker delta function as:

$$H(i) = \sum_n^{N-1} \sum_m^{M-1} \delta(p[m, n], i) \quad \text{for } i = 0, 1, \dots, L - 1 \quad (28.1)$$

where

$$\delta(p[m, n], i) = \begin{cases} 1, & \text{for } p[m, n] = i \\ 0, & \text{for } p[m, n] \neq i \end{cases} \quad (28.2)$$

Histogram is used for defining first order statistical features of the image, such as mean value  $\mu_H$ , variance  $\sigma_H$ , skewness, kurtosis, energy, and entropy. The definitions of these parameters are given below.

$$\begin{aligned} \mu_H &= \sum_{i=0}^{L-1} ip(i) \\ \sigma_H &= \sum_{i=0}^{L-1} (i - \mu_H)^2 p(i) \\ \text{skewness} &= \frac{\sum_{i=0}^{L-1} (i - \mu_H)^3 p(i)}{\sigma_H^3} \\ \text{kurtosis} &= \frac{\sum_{i=0}^{L-1} (i - \mu_H)^4 p(i)}{\sigma_H^4} - 3 \\ \text{energy} &= \sum_{i=0}^{L-1} p^2(i) \\ \text{entropy} &= - \sum_{i=0}^{L-1} \log_2(p(i))p(i) \end{aligned} \tag{28.3}$$

Histogram gives global information on an image. By converting histogram we can obtain some very useful image improvement, such as contrast enhancement [1,14]. The first order statistical parameters can be used to separate physiological and pathological breast thermal images. The results for breast cancer screening are presented below.

Thirty-two healthy patients and ten patients with malignant tumors were analyzed using thermography. There were four images registered for every patient that represented each breast in direct and lateral direction to the camera. Histograms were created for these images and on the basis of statistical parameters, the following features were calculated: mean temperature, standard deviation, variance, skewness, and kurtosis. Afterward, differences of parameter values for left and right breast were calculated. The degree of symmetry on the basis of these differences was then estimated (see Figure 28.5 and Figure 28.6).

FIGURE 28.5 Histograms of healthy breast thermographs.

**FIGURE 28.6** Histograms of breast thermographs with malignant tumor.

The mean temperature in the healthy group was estimated at the level  $30.2 \pm 1.8^\circ\text{C}$  in the direct position and  $29.7 \pm 1.9^\circ\text{C}$  in the lateral one. The mean temperature was higher in 8 cases out of 10 in malignant tumor group. Moreover, 6 cases out of 32 in the healthy group with mean temperatures exceeded normal level. Therefore, we have found that it is necessary to analyze symmetry between left and right breast. Comparison of mean temperature was not sufficient to separate physiological and pathological images. Among analyzed parameters, skewness was the most promising for successful classification of thermal images. Absolute differences of skewness for left and right side was equal to  $0.4 \pm 0.3^\circ\text{C}$  in frontal position and  $0.6 \pm 0.4^\circ\text{C}$  in lateral one for the healthy group. These differences were higher for images in lateral position in all cases in the pathological group in comparison to the healthy patients' images.

The image in Figure 28.4 confirm the evidence of asymmetry between left and right side for healthy and malignant tumor cases.

Analyzing the first order statistical parameter let us conclude that it is quite hard to use them for the image classification and detecting tumors. In some cases, only mean temperature and the skewness let us to separate and classify thermal images of breasts with and without malignant tumors. Frontal and lateral positions were used during this investigation, but no significant difference of the obtained result was noticed.

It is concluded that the first order parameters do not give the satisfactory results, and due to some physiological changes of the breast, we could observe that these parameters do not allow separating patients with and without tumors. That was the main reason, that the second order statistical parameters are used for the further investigations.

## 28.2 Second Order Statistical Parameters

More advanced statistical information on thermal images can be derived from second order parameters. They are defined on so-called co-occurrence matrix. Such a matrix represents the joint probability of two pixels having  $i$ -th and  $j$ -th intensity at the different distances  $d$ , in the different directions. Co-occurrence matrix gives more information on intensity distribution over the whole image, and in this sense, it can effectively be used to separate and classify thermal images.

Let us assume that each pixel has eight neighbors lying in four directions: horizontal, vertical, diagonal and antidiagonal. Let us consider only the nearest neighbors, so the distance  $d = 1$  (see Figure 28.7).

As an example let us take an image  $4 \times 4$  with 4 intensity levels given as (see Figure 28.8).

FIGURE 28.7 Eight neighboring pixels in four direct horizontal, vertical, diagonal, and antidiagonal.

FIGURE 28.8 Example of  $4 \times 4$  image with 4 discrete intensity levels.

FIGURE 28.9 Difference variance vs. variance obtained from co-occurrence matrix for horizontal direction.

For horizontal direction the co-occurrence matrix takes a form:

$$m_{\text{horizontal}} = \begin{bmatrix} 2 & 1 & 0 & 0 \\ 1 & 4 & 2 & 2 \\ 0 & 2 & 4 & 2 \\ 0 & 2 & 2 & 0 \end{bmatrix} \tag{28.4}$$

The co-occurrence matrix is always square and diagonal with the dimension equal to the number of intensity levels in the image. After normalization, we get the matrix of the probabilities  $p(i, j)$ . Normalization is done by dividing the all elements by number of possible couple pixels for a given direction of analysis. For horizontal and vertical directions this number is equal to  $2N(M - 1)$  and  $2M(N - 1)$ , while for diagonal directions it is  $2(M - 1)(N - 1)$ , respectively.

Second order parameters are presented by Equation 28.4 and Equation 28.6. As an example of comparing thermal images  $\mu_x, \mu_y, \sigma_x, \sigma_y$  are mean values and standard deviations for the elements of co-occurrence matrices that were calculated for horizontal and vertical directions, respectively, and the results are presented in Figure 28.9 and Figure 28.10.

FIGURE 28.10 Difference variance vs. variance obtained from co-occurrence matrix for diagonal direction.

Second order statistical parameters can be used to discriminate the physiological and pathological cases, for example, breast cancers. Most of them successfully discriminate healthy and malignant tumor cases. The protocol of the investigation assumes the symmetry analysis in the following way. At first, the square ROI were chosen for analysis. Then, co-occurrence matrixes were calculated for left and right breasts to evaluate second order statistical parameters for different directions. Only the neighboring pixels are considered in these investigations ( $d = 1$ ). Finally, the differences of the values of these parameters for left and right sides were used for the image classification. Figure 28.9 and Figure 28.10 illustrate that the differences of second order parameters for left and right sides are typically greater for pathological cases. Taking two parameters such as difference variance and variance allows successfully separating almost all healthy and malignant tumor cases.

$$\begin{aligned}
 \text{Energy} &= \sum_{i=0}^{L-1} \sum_{j=0}^{L-1} p^2(i, j) \\
 \text{Variance} &= \sum_{i=0}^{L-1} \sum_{j=0}^{L-1} (i - j)^2 p(i, j) \\
 \text{Difference variance} &= \text{Var}(p_{x-y})
 \end{aligned}
 \tag{28.5}$$

where

$$\begin{aligned}
 p_{x-y}(l) &= \sum_{i=0}^{L-1} \sum_{j=0}^{L-1} p(i, j), \quad \text{for } |i - j| = l, \quad l = 0, 1, \dots, G - 2 \\
 \text{Correlation} &= \frac{\sum_{i=0}^{L-1} \sum_{j=0}^{L-1} (ij) p(i, j) - \mu_x \mu_y}{\sigma_x \sigma_y} \\
 \text{Inverse difference} &= \sum_{i=0}^{L-1} \sum_{j=0}^{L-1} \frac{p(i, j)}{1 + (i - j)^2} \\
 \text{Entropy} &= - \sum_{i=0}^{L-1} \sum_{j=0}^{L-1} p(i, j) \log_2[p(i, j)]
 \end{aligned}
 \tag{28.6}$$

### 28.3 Wavelet Transformation

Wavelet transformation is actually used in many domains, such as telecommunication and signal processing for compression and to extract quantitative features from the signal. In image processing it can be employed to get new features, representing both global and detail information. Wavelet transformation is based on image filtering represented by rows and columns using low and high pass linear filters (Figure 28.11). After filtering, decimation is used to reduce the number of pixels. The procedure can be repeated until  $1 \times 1$  images are obtained. Practically, the processing is stopped earlier, after 2 to 4 steps, and then the features are derived from the filtered subimages.

As an example, the investigations of 10 patients with recognized breast tumors, as well as 30 healthy patients are presented. All healthy and pathological cases were confirmed by other diagnostic methods, such as mammography, USG, biopsy, and so on. We have used thermographic camera to take two images for each breast: frontal and side ones. Each patient was relaxing before the experiment for 15 min in a room where temperature were stabilized at  $20^{\circ}\text{C}$ .

Then the numerical procedure was used to calculate features of the images. Figure 28.12 presents the pathological case where left breast has evidently higher temperature and the temperature distribution is very asymmetric.

One of the possible transformations uses wavelets realized by filtering as it has already been mentioned. The result of such processing is presented in Figure 28.13. As it is seen, the different filters are showing different details of the image, that is, high pass filters allows to present gradient of the temperature, while

FIGURE 28.11 Wavelet transformation of an image.

FIGURE 28.12 (See color insert.) Example of thermal image with the tumor.

**FIGURE 28.13** Result of wavelet transformation.

the low pass ones display the global temperature distribution and the energy of the signal understood as the level of temperature.

As a powerful tool, wavelet transformation gives the possibility of generating new features from different subimages, in different scales and subbands. Filtering can be easily parameterized in the sense of varying cutoff frequency, what provides the additional flexibility in the algorithm. It denotes, that a lot of different features can be produced by this method. Obviously, the selection of these features is necessary to obtain only these ones, which are the most discriminative and weakly correlated [11].

## 28.4 Classification

Artificial neural network are typically used for classification. The selected image features are used as inputs. It means that the number of input nodes is equal to number of the features. The number of neurons in the first hidden layer can be equal or lower than the number of features in the classification, as shown in Figure 28.14. ANN can have user-defined next hidden layers, which allow additional nonlinear processing of the input features. As ANN is the nonlinear system, such technique allows to additional decorrelating and data reduction, what in consequence improves the classification. Such approach is known as nonlinear discriminant analysis (NDA) [3,11].

It is well known that the training of ANN is the very important step in the entire protocol. It is an multivariable optimization problem typically based on back-propagation technique. In general case it can lead to wrong solutions if the there is no single minimum of the error function. That is why we need enough data during learning phase, and sometimes it is better or necessary to repeat training of ANN with different initial values of the neuron weight coefficients.

Classification can start from the raw data analysis. As seen in Figure 28.15, two classes of images containing (1) nonhealthy and (2) healthy cases are chosen. In this example, selection of features reduces the number of features to two, derived from the co-occurrence matrix (sum of squares and inverse difference moment) [1,10,12]. The third one is based on wavelet transformation — energy  $E_{HL}$  for the scale no.1 and high and low frequency subbands. Raw data analysis (Figure 28.15) does not give satisfactory feature separation and classification. It is hard to separate clusters of features corresponding to physiological and pathological images. The distance in between them in the multivariate space is not large enough, which means that the probability of erroneous classification is still quite high.

The next results were obtained by LDA (Figure 28.16), in which the most discriminative features (MDF) are generated [10,13]. LDA creates typically new set with smaller number of features. LDA is the linear

FIGURE 28.14 Neural network example with input, single hidden, and output layers.

FIGURE 28.15 Raw data analysis result.

transformation, and produces linearly separated features, which means that in general case it is also not possible to separate them fully. This case is illustrated in Figure 28.16.

Nonlinear transformation of the features obtained by ANN with additional hidden layer is the most promising technique. The output of this additional hidden layer creates the new smaller set of features, which are typically much better separable. It can be simple verified by the larger value of Fisher coefficient. In our investigation, seven original features were selected using POE and ACC selection criteria. The first and second hidden layers contained only one and two neurons, respectively. It denotes that the original features were reduced to two new ones. The expectation that this approach allows better separation and classification is now confirmed [2].

The results of NDA are presented in Figure 28.17 and Figure 28.18. Two new features are far away from each other on the feature space, both for frontal and side images. It is even not very surprising that the value of Fisher coefficient  $F = 2.7$  for original features is now increased to  $F = 443.4$ . ANN together with

FIGURE 28.16 Nonacceptable separation of cluster using LDA.

FIGURE 28.17 NDA classification results for side thermal images of the breast.

FIGURE 28.18 NDA classification results for frontal thermal images of the breast.

NDA have one more advantage. Besides data reduction and decorrelating, it also allows implementing classification realized by the last output layer of ANN.

We faced one problem in the presented research. The number of pathological cases was small, only ten. As it has been already mentioned it is difficult to get well diagnosed patients, especially in the young age [4–6]. The research is still in progress, and we actually enlarging our image database day-by-day. This research is a preliminary one, and shows the possibility of using advanced image processing tools. The effectiveness of the screening procedure can be verified later, when we will have enough input data.

Because of the above limits, the classification was carried out in the following simplified way: First we have chosen equal number of physiological and pathological images, that is, 10 + 10. Every image from

**TABLE 28.1** Errors of Classification

	Frontal positions		Side positions	
	False negative	False positive	False negative	False positive
Raw data	2/10	3/30	1/10	2/30
PCA	2/10	3/30	1/10	2/30
LDA	1/10	2/30	1/10	1/30
NDA	2/10	2/30	0/10	2/30

each class (healthy and nonhealthy) was extracted, and the training of ANN was performed for all the rest. Then this one not being used before during learning was employed now for classification.

The results are presented in Table 28.1. First three rows in this table present nearest neighbor (NN) classification of the image features. The first results were obtained by using feature calculated on a image and NN classification after feature selection. In the subsequent experiments, preprocessing of original features using PCA and LDA was employed.

Finally, calculation using NDA was performed with an additional hidden layer that consisted of two neurons for generating two new more discriminative features. The results in Table 28.1 confirm the effectiveness of using both NN and ANN classifiers. Although it was not evidently proved that NDA results are better in the classification, we definitely conclude that ANN is a powerful tool for thermal image processing during breast cancer screening. Reducing false/positive errors of classification is the most important task for the future research.

## 28.5 Conclusion

This chapter presents the preliminary results of the feature analysis for thermal images for different medical applications, mainly used in breast oncology. Thermography as the additional and adjacent method can be very helpful for early screening that helps to recognize tumors. At first, we consider first and second order statistical parameters. Although we do not have many pathological cases for investigations yet, the first results are very promising. The second order parameters are more sensitive to the overall structure of an image. Actually, the study is being extended by choosing second order parameters for multivariate data classification. The presented approach includes the PCA to reduce the dimensionality of the problem and by selecting the eigen vectors it is possible to generate data, which represents the tumors more evidently.

Breast cancer screening is a challenge today for medical engineering. Breast temperature depends not only due to some pathological changes, but it also varies in normal physiological situations, it is even a consequence of emotional state of a patient. It was a main reason that we are looking for more advanced methods of thermal image processing, that could give satisfactory results.

One of the possible alternative for such processing is ANN classification based on multidimensional feature domain, with use of modern transformations, such as wavelets. The preliminary investigations are quite successful, and can be improved by increasing the number of samples taken for processing.

Future research will concentrate around selection of features and adjusting wavelet transformation parameters to get the best classification. We assume that the more satisfactory results can be obtained by using features based on asymmetry between left and right sides of a patient. It could help for one-side cancerous lesion classification, what is the most typical pathological case and frequently happens today.

### 29.1 Introduction

---

Biometrics has received a lot of attention in the last few years both from the academic and business communities. It has emerged as a preferred alternative to traditional forms of identification, like card IDs, which are not emedded into one's physical characteristics. Research into several biometric modalities including face, fingerprint, iris, and retina recognition has produced varying degrees of success [1]. Face recognition stands as the most appealing modality, since it is the natural mode of identification among humans and totally unobtrusive. At the same time, however, it is one of the most challenging modalities [2]. Faces are 3D objects with rich details that vary with orientation, illumination, age, and artifacts (e.g., glasses).

Research into face recognition has been biased towards the visible spectrum for a variety of reasons. Among those is the availability and low cost of visible band cameras and the undeniable fact that face recognition is one of the primary activities of the human visual system. Machine recognition of human faces, however, has proved more problematic than the seemingly effortless face recognition performed by humans. The major culprit is light variability, which is prevalent in the visible spectrum due to the reflective nature of incident light in this band. Secondary problems are associated to the difficulty of detecting facial disguises [3].

As a cure to the aforementioned problems, researchers have started investigating the use of thermal infrared for face recognition purposes [4,5]. Efforts were directed into solving three complementary problems: face detection, feature extraction, and classification (see Figure 29.1) [6,7]. Face detection is a

prerequisite step, since a face cannot be recognized unless first it is detected in the scene. Feature extraction follows face detection and reduces the face to a succinct mathematical description — the feature vector. Classification operates upon the feature vector and matches the incoming face to one of the records kept in the database.

Many of the research efforts in thermal face recognition use the thermal infrared band as a way to see in the dark or reduce the deleterious effect of light variability [8]. Methodologically, they do not differ very much from face recognition algorithms in the visible band [9]. In this chapter, we will present a novel approach to the problem of thermal facial recognition that realizes the full potential of the thermal infrared band. It consists of a statistical face detection and physiological feature extraction algorithm tailored to thermal phenomenology. We will not elaborate on classification, since we do not have to add anything new in this part of the face recognition process. Our goal is to promote a different way of thinking in areas where thermal infrared should be approached in a distinct manner with respect to other modalities.

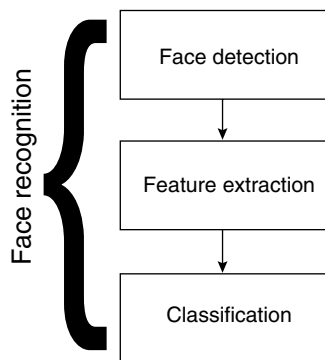

## 29.2 Face Detection in Thermal Infrared

We approach the face detection problem in thermal infrared from a statistical point of view. Due to its physiology, a typical human face consists of *hot* and *cold* parts. Hot parts correspond to tissue areas that are rich in vasculature (e.g., periorbital and forehead). Cold parts correspond to tissue areas that feature either sparse vasculature or multi-sided exposure to the environment (e.g., cheeks and nose). This casts the human face as a bimodal distribution entity. The background can also be described by a bimodal distribution. It typically consists of walls (*cold* objects) and the upper part of the subject's body dressed in clothes (*hot* objects). The bimodal distributions of the face and background vary over time, due to thermophysiological processes and environmental noise respectively. Therefore, the problem renders itself naturally to the Bayesian framework, since we have a priori knowledge of the bimodal nature of the scene, which can be updated over time by the incoming evidence (new thermal frames from the camera).

### 29.2.1 Facial Tissue Delineation Using a Bayesian Approach

We consider an indoor area that is being monitored with a thermal infrared camera. The objective is to detect and delineate a human face should this become available in the scene. The segmented face data feed the feature extraction and classification modules, which complete the face recognition process (see Figure 29.1). Initially, we consider the face detection problem at the pixel level and label every pixel as either facial skin *s* or background *b* pixel.

In more detail, we use a mixture of two Normal distributions to model facial skin temperature. The dominant mode is in the upper band of the values where usually about 60 to 70% of the probability mass

**FIGURE 29.1** Architecture of a face recognition system. We will focus on face detection and feature extraction, where thermal infrared warrants a totally different approach from the one usually undertaken in the literature.

**FIGURE 29.2** Temperature distributions of exposed skin and background from a set of facial thermal images in the University of Houston database. The bimodal nature of the distributions is evident.

resides. The secondary mode is in the lower band of the values. For subjects in climate controlled rooms a typical temperature range for the dominant skin mode is  $\sim(32\text{--}35)^\circ\text{C}$ , while for the secondary mode is  $\sim(28\text{--}30)^\circ\text{C}$ . The latter may overlap with the background distribution since areas of the face like the nose and ears have temperatures similar to the environment (see Figure 29.2).

Similarly, we use a mixture of two Normal distributions to model background temperature. The dominant mode is in the lower band of the values where about 80% of the background probability mass resides (typically, in the range  $\sim[27\text{ to }29]^\circ\text{C}$ ). The secondary background mode has its mean somewhere between the two modes of the skin distribution and variance large enough to cover almost the entire band. Therefore, the secondary background distribution includes some relatively high temperature values. These are due to the fact that light clothes offer spots of high temperature (e.g., places where the clothes touch the skin), which mimic the skin distribution but are not skin (see Figure 29.2).

For each pixel we have some prior distribution (information) available of whether this particular pixel represents skin ( $\pi(s)$ ) or background ( $\pi(b) = 1 - \pi(s)$ ). Then, the incoming pixel value represents the data (likelihood) that will be used to update the prior to posterior distribution via the Bayes theorem. Based on the posterior distribution we will draw our inference of whether the specific pixel represents  $s$  or  $b$ . At the end, this posterior distribution will be used as the prior for the next incoming data point.

We call  $\theta$  the parameter of interest, which takes two possible values ( $s$  and  $b$ ) with some probability. The prior distribution at time  $t$  consists of the probabilities of the two complementary events,  $s$  and  $b$ . Thus, we have:

$$\pi^{(t)}(\theta) = \begin{cases} \pi^{(t)}(s), & \text{when } \theta = s \\ \pi^{(t)}(b) = 1 - \pi^{(t)}(s), & \text{when } \theta = b \end{cases} \quad (29.1)$$

The incoming pixel value  $x_t$  has a conditional distribution  $f(x_t|\theta)$ , which depends on whether the particular pixel is skin (i.e.,  $\theta = s$ ) or background (i.e.,  $\theta = b$ ). Based on our bimodal view of the skin and background distributions we will have for the likelihood:

$$f(x_t|\theta) = \begin{cases} f(x_t|s): \omega_s^{(t)}N(\mu_{s_1}^{(t)}, \sigma_{s_1}^{2(t)}) + (1 - \omega_s^{(t)})N(\mu_{s_2}^{(t)}, \sigma_{s_2}^{2(t)}), & \text{when } \theta = s \\ f(x_t|b): \omega_b^{(t)}N(\mu_{b_1}^{(t)}, \sigma_{b_1}^{2(t)}) + (1 - \omega_b^{(t)})N(\mu_{b_2}^{(t)}, \sigma_{b_2}^{2(t)}), & \text{when } \theta = b \end{cases} \quad (29.2)$$

There are ten parameters that are involved in the conditional distribution of Equation 29.2, namely, 2 weights, 4 means, and 4 variances. We will discuss later on, how to initialize and update these parameters.

The prior distribution,  $\pi^{(t)}(\theta)$ , will be combined with the likelihood,  $f(x_t | \theta)$ , to provide (via the Bayes theorem) the posterior distribution  $p^{(t)}(\theta | x_t)$ . Thus, we will have:

$$p^{(t)}(\theta | x_t) = \begin{cases} p^{(t)}(s | x_t), & \text{when } \theta = s \\ p^{(t)}(b | x_t) = 1 - p^{(t)}(s | x_t), & \text{when } \theta = b \end{cases} \quad (29.3)$$

where according to the Bayes theorem:

$$p^{(t)}(s | x_t) = \frac{\pi^{(t)}(s)f(x_t | s)}{\pi^{(t)}(s)f(x_t | s) + \pi^{(t)}(b)f(x_t | b)} \quad (29.4)$$

In the Bayesian philosophy the posterior distribution of the parameter of interest represents how the prior information (distribution) is updated in light of new evidence (data). At every time point  $t$  our inference (on whether the particular pixel represents  $s$  or  $b$ ) will be based on the posterior distribution,  $p^{(t)}(\theta | x_t)$ .

This posterior distribution will also be used to provide the prior distribution for the next stage. More precisely:

$$\pi^{(t+1)}(\theta) = \begin{cases} \pi^{(t+1)}(s) = p^{(t)}(s | x_t), & \text{when } \theta = s \\ \pi^{(t+1)}(b) = p^{(t)}(b | x_t) = 1 - \pi^{(t+1)}(s), & \text{when } \theta = b \end{cases} \quad (29.5)$$

### 29.2.1.1 Initialization

As part of the initialization, we need to specify two things: the prior distribution,  $\pi^{(1)}(\theta)$  and the likelihood  $f(x_1 | \theta)$ . Absence of information on whether a pixel is skin or background, leads us to adopt a noninformative prior distribution where a priori each pixel is equally likely to be  $s$  or  $b$ . Thus, we have:

$$\pi^{(1)}(s) = \frac{1}{2} = \pi^{(1)}(b) \quad (29.6)$$

Regarding the likelihood, we need to calculate the initial values of the ten parameters involved in the likelihood Equation 29.2. For that, we select  $N$  facial frames (off-line) from a variety of subjects. This is the so-called training set. It is important for this set to be representative, that is, to include people of both sexes, different ages, and with different physical characteristics. We manually segment on all the  $N$  frames, skin and, background areas (see Figure 29.3). The segmentation needs to be representative. For example,

**FIGURE 29.3** (See color insert following page 29-16.) Manual segmentation of skin (black rectangles) and background (white rectangles) areas for initialization purposes.

in the case of skin areas, we need to include eyes, ears, nose and the other facial areas, not parts thereof. Out of the  $N$  frames the segmentation will yield  $N_s$  skin and  $N_b$  background pixels.

For the skin distribution we have available at the initial state the pixels  $x_1, x_2, \dots, x_{N_s}$ , which are assumed to be sampled from a mixture of two Normal distributions:

$$f(x_j | s) = \sum_{i=1}^2 \omega_{s_i} N(\mu_{s_i}, \sigma_{s_i}^2) \tag{29.7}$$

where  $\omega_{s_2} = 1 - \omega_{s_1}$ . We estimate the mixture parameters  $\omega_{s_i}, \mu_{s_i}$ , and  $\sigma_{s_i}^2$  using the  $N_s$  skin pixels of the training set via the EM algorithm. Initially, we provide the EM algorithm with some crude estimates of the parameters of interest:  $\omega_{s_i}^{(0)}, \mu_{s_i}^{(0)}$ , and  $(\sigma_{s_i}^{(0)})^2$ . Then, we apply the following loop: For  $k = 0, 1, \dots$ , we calculate:

$$z_{ij}^{(k)} = \frac{\omega_{s_i}^{(k)} (\sigma_{s_i}^{(k)})^{-1} \exp \left\{ -\frac{1}{2(\sigma_{s_i}^{(k)})^2} (x_j - \mu_{s_i}^{(k)})^2 \right\}}{\sum_{t=1}^2 \omega_{s_t}^{(k)} (\sigma_{s_t}^{(k)})^{-1} \exp \left\{ -\frac{1}{2(\sigma_{s_t}^{(k)})^2} (x_j - \mu_{s_t}^{(k)})^2 \right\}} \tag{29.8}$$

$$\omega_{s_i}^{(k+1)} = \frac{\sum_{j=1}^{N_s} z_{ij}^{(k)}}{N_s} \tag{29.9}$$

$$\mu_{s_i}^{(k+1)} = \frac{\sum_{j=1}^{N_s} z_{ij}^{(k)} x_j}{N_s \omega_{s_i}^{(k+1)}} \tag{29.10}$$

$$(\sigma_{s_i}^{(k+1)})^2 = \frac{\sum_{j=1}^{N_s} z_{ij}^{(k)} (x_j - \mu_{s_i}^{(k+1)})^2}{N_s \omega_{s_i}^{(k+1)}} \tag{29.11}$$

for  $i = 1, 2$  and  $j = 1, \dots, N_s$ . Then, we set  $k = k + 1$  and repeat the loop. The condition for terminating the loop is:

$$|\omega_{s_i}^{(k+1)} - \omega_{s_i}^{(k)}| < \varepsilon \quad i = 1, 2 \tag{29.12}$$

where  $\varepsilon$  is a small positive number ( $10^{-3}, 10^{-4}, \dots$ ). We apply a similar EM process for determining the initial parameters of the background distributions.

**29.2.1.2 Inference**

Once a data point  $x_t$  becomes available we are faced with the decision of whether the particular pixel represents skin or background. In a decision theory framework this can be cast as testing the statistical hypotheses for the parameter of interest  $\theta$ :

$$\left\{ \begin{array}{l} H_0: \theta = s \text{ (i.e., the pixel represents skin)} \\ H_1: \theta = b \text{ (i.e., the pixel represents background)} \end{array} \right\}$$

Using Equation 29.2 and Equation 29.4 we combine the data with the prior distributions to obtain the posterior distributions. Our inference will be based on these posterior distributions. We need to decide whether we will accept  $H_0$  or  $H_1$ . The easiest way to do this within the Bayesian framework is to favor the hypothesis that has the highest a posteriori coverage. That simply means:

$$\left\{ \begin{array}{l} \text{Accept } H_0 \text{ if: } p^{(t)}(s | x_t) > p^{(t)}(b | x_t) \Leftrightarrow p^{(t)}(s | x_t) > 0.5 \\ \text{Accept } H_1 \text{ if: } p^{(t)}(s | x_t) < p^{(t)}(b | x_t) \Leftrightarrow p^{(t)}(s | x_t) < 0.5 \end{array} \right\}$$

**FIGURE 29.4** (See color insert.) Visualization of Bayesian segmentation on a subject: (a) original image; (b) segmented image. The nose has been erroneously segmented as background and a couple of hair patches have been erroneously marked as facial skin. This is due to occasional overlapping between portions of the skin and background distributions. The isolated nature of these mislabeled patches makes them easily correctable through post-processing.

Figure 29.4 visualizes the results of Bayesian segmentation on a typical facial thermal image from the University of Houston database.

### 29.3 Facial Feature Extraction in Thermal Infrared

Once the face is delineated from the rest of the scene, one can extract the features necessary for classification. In contrast to the visible band, thermal infrared provides the capability to extract physiological features. In particular, blood that flows in the major superficial vessels creates a substantial convective heat effect that is manifested in thermal imagery. Segmentation of the vascular network can provide the basis of a unique feature vector. The topology and extent of the recovered vascular network depend on the genetic traits and physical characteristics of the individual (e.g., facial skin fat deposits). Therefore, facial vasculature is an identifying entity that endures through aging and superficial changes of appearance.

The problem for vessel segmentation has been solved in other imaging modalities using a variety of methods. To the best of our knowledge, it is the first time that vessel segmentation is reported in the thermal imaging modality. In our effort, we took into account methodologies used for vessel segmentation in modalities other than thermal imaging (e.g., ultrasound and MRI). We can broadly categorize these methodologies as follows:

- Center line detection approaches
- Ridge-based approaches
- Region growing approaches
- Differential geometry-based approaches
- Matched filter approaches
- Mathematical morphology approaches

In the center line extraction scheme, the vasculature is developed by traversing the vessels' center lines. The method employs thresholding and thinning of the image, followed by connected component analysis. Center line extraction techniques are used by References 10 and 11. They use graph search theory to find out vessel center lines and then curvature features to reconstruct the vasculature. In Reference 12, the authors detect center lines from images acquired from different angles. As a result, they are able to represent the 3D shape of the vessels.

Ridge-based approaches convert a 2D gray scale image into a 3D surface by mapping the intensity values along the  $z$ -axis. Once the surface is generated, the local ridge points are those where the directional gradient is the steepest. The ridges are invariant to affine transforms and this property is exploited in

medical registration [13,14]. The method of segmentation of vessels using the ridge-based approach is discussed in Reference 15 and more extensive details are available in its references.

One of the most widely used methods of vessel segmentation is the region growing method. Traditionally, the parameters used for growing the vessel region are pixel intensity and proximity. Recent improvements in this method include gradient and texture [16,17]. Such methods, although they give good results, depend upon initialization. In Reference 18, based on the starting seed provided by the user the region grows upon similar spatial, temporal, and structural features. A similar method is also used in Reference 19.

If a 2D image is mapped into a 3D surface, then the crest lines are the most salient features of that surface. This gives rise to the differential geometry based methods for vessel segmentation. The crest lines are obtained by linking the crest points in the image, which are the local maxima of the surface curvature. A prominent differential geometry-based method is the directional anisotropic diffusion (DAD), which is discussed in Reference 20. It uses Gaussian convolution to remove the image noise. This method is a generalized form of the method reported in Reference 21 and uses the gradient as well as the minimum and maximum curvature information to differentiate the diffusion equation. The method removes the noise without blurring and is thus, very useful in edge enhancement procedures.

The matched filtering approach uses a series of Gaussian kernels of different sizes and orientations. In Reference 22 the orientation of the Gaussian filters is chosen using the Hessian matrix. A similar approach is used in Reference 23 to enhance and detect vessels in real time. These methods are similar to the Gabor filters, which are extensively used in texture analysis.

### 29.3.1 Morphological Reconstruction of Superficial Blood Vessels

In our method, first, we smooth the image to remove the unwanted noise and then, we apply the morphological operators. In thermal imagery of human tissue the major blood vessels do not have strong edges. Due to the thermal diffusion process the edges that we get have a sigmoid temperature profile. A sigmoid function can be written as  $y = 1/(1 + e^{-x})$  (see Figure 29.5).

The method of anisotropic diffusion has proved very effective in handling sigmoid edges [24,25]. Nonlinear anisotropic diffusion filters are iterative filters introduced by Perona et al. [21]. Greig et al. [26] used such filters to enhance MR images. Sapiro et al. [27] used a similar technique to perform edge preserving smoothing of MR images. Others have shown that diffusion filters can be used to enhance and detect object edges within images [21,28].

FIGURE 29.5 Sigmoid function plot.

The anisotropic diffusion filter is formulated as a process that enhances object boundaries by performing intra-region as opposed to inter-region smoothing. The mathematical equation for the process is:

$$\frac{\partial I(\bar{x}, t)}{\partial t} = \nabla(c(\bar{x}, t)\nabla I(\bar{x}, t)) \quad (29.13)$$

In our case  $I(\bar{x}, t)$  is the thermal image,  $\bar{x}$  refers to the spatial dimensions, and  $t$  to time. The function  $c(\bar{x}, t)$  is a monotonically decreasing function of the image gradient magnitude and is called the *diffusion function*

$$c(\bar{x}, t) = f(|\nabla I(\bar{x}, t)|) \quad (29.14)$$

This allows locally adaptive diffusion strengths. Edges are thus, selectively smoothed or enhanced on the basis of the evaluated diffusion function.

Perona and Malik have suggested the following two formulations for the diffusion function:

$$c_1(\bar{x}, t) = \exp\left(-\left(\frac{|\nabla I(\bar{x}, t)|}{k}\right)^2\right) \quad (29.15)$$

$$c_2(\bar{x}, t) = \exp\left(\frac{1}{1 + \left(\frac{|\nabla I(\bar{x}, t)|}{k}\right)^{1+\alpha}}\right) \quad (29.16)$$

Typical responses of the thermal image of the wrist to the Perona–Malik filters with diffusion functions  $c_1$  and  $c_2$  respectively are shown in Figure 29.6. One can observe that for the same image gradient and value of the  $k$  parameter a steeper slope is obtained for  $c_1$  as compared to  $c_2$ .

The discrete version of the anisotropic diffusion filter of Equation 29.13 is as follows:

$$I_{t+1}(x, y) = I_t + \frac{1}{4} \times [c_{N,t}(x, y)\nabla I_{N,t}(x, y) + c_{S,t}(x, y)\nabla I_{S,t}(x, y) + c_{E,t}(x, y)\nabla I_{E,t}(x, y) + c_{W,t}\nabla I_{W,t}(x, y)] \quad (29.17)$$

The four diffusion coefficients and gradients in Equation 29.17 correspond to four directions (i.e., North, South, East, and West) with respect to location  $(x, y)$ . Each diffusion coefficient and the corresponding gradient are calculated in a similar manner. For example, the coefficient along the north direction is calculated as:

$$c_{N,t}(x, y) = \exp\left(\frac{-\nabla I_{N,t}^2(x, y)}{k^2}\right) \quad (29.18)$$

where  $\nabla I_{N,t} = I_t(x, y + 1) - I_t(x, y)$ .

Figure 29.7a,b show the original thermal image of skin tissue (wrist in this case) and its temperature surface plot respectively. One can observe in the surface plot the noisy ridges formed due to the hair. Figure 29.7c shows the filtered skin image. The hair has been removed from the surface, resulting into smoother ridges and heightened peaks in the temperature surface plot (Figure 29.7d).

As these figures testify anisotropic diffusion is highly beneficial in improving the contrast in the image and removing the noise. This is in preparation of vessel segmentation through morphological methods.

### 29.3.1.1 Image Morphology

Image morphology is a way of analyzing imagery based on shapes. It is rooted on set theory, the Minkowski operators, and DeMorgan's Laws. The Minkowski operators are usually applied to binary images where it

**FIGURE 29.6** (a) Plot of diffusion function  $c_1$  against the image gradient. (b) Plot of diffusion function  $c_2$  against the image gradient.

is easy to perform OR and AND operations. The same operators can be applied to gray scale images with small modifications.

Image morphology is a simple but effective tool for shape analysis and segmentation. In retinotherapy it has shown great results in localization of blood vessels in the retina. Leandro et al. [29] have used morphological operators for vessel delineation in the retina where the background intensity was very close to that of the blood vessels. In our case, we have the blood vessels, which have a relatively low contrast compared to that of the surrounding tissue. As per our hypothesis the blood vessel is a tubule like structure running either along the length of the forearm or the face. Thus, our problem is to segment tubule structures from the image. We employ for this purpose a top-hat segmentation method, which is a combination of erosion and dilation operations.

**FIGURE 29.7** (See color insert.) (a) Original thermal image of a wrist. (b) Temperature surface plot of the original image. (c) Diffused thermal image of the wrist. (d) Temperature surface plot of the diffused image.

**FIGURE 29.8** Structuring elements.

Erosion and dilation are the two most basic operations in mathematical morphology. Both of these operations take two pieces of data as input: an image to be eroded or dilated and a structuring element. The structuring element is similar to what we know as a kernel in the convolution operation. There are a variety of structuring elements available but a simple  $3 \times 3$  square matrix is used more often. Figure 29.8 shows some commonly used structuring elements.

The combination of erosion and dilation results into more advanced morphological operations such as:

- Opening
- Closing
- Skeletonization

FIGURE 29.9 Binary erosion by a  $3 \times 3$  flat structuring element.

- White top hat segmentation
- Black top hat segmentation

In our application, we are interested only in image opening and top hat segmentation.

1. *Erosion*: The name suggests that this operation erodes the boundary pixels of an image and thus, the resultant image has a shrunk boundary. Mathematically, it is defined as follows:

$$A \oplus B = \{z \mid (A \cap B)_z \subseteq B\} \tag{29.19}$$

Therefore, erosion removes elements smaller than the structuring element. Figure 29.9 shows a simple erosion operation performed on a binary image. Gray scale erosion with a flat structuring element generally darkens the image. Bright regions surrounded by dark regions shrink in size and dark regions surrounded by bright regions grow in size. Small bright spots in images disappear, as they are eroded away down to the surrounding intensity value. In contrast, small dark spots grow. The effect is most pronounced at places in the image where the intensity changes rapidly. Regions of fairly uniform intensity are left more or less unchanged except at their edges.

2. *Dilation*: The name suggests that this operation gradually expands the boundary pixels of an image and thus, the resultant image will have an enlarged boundary. Dilation results in fusing small holes in the boundary area, by enlarging the boundary pixels. This is the equivalent of a smoothing function. Mathematically, it is defined as follows:

$$A \oplus B = \{z \mid (\cap B)_z \cap A \neq \emptyset\} \tag{29.20}$$

Therefore, dilation fills in gaps smaller than the structuring element. Figure 29.10 shows a simple dilation operation performed on a binary image. Gray scale dilation with a flat structuring element generally brightens the image. Bright regions surrounded by dark regions grow in size and dark regions surrounded by bright regions shrink in size. Small dark spots in images disappear as they are “filled in” to the surrounding intensity values. In contrast, small bright spots will grow in size. The effect is most pronounced at places in the image where the intensity changes rapidly. Regions of fairly uniform intensity will be largely unchanged except at their edges.

3. *Opening*: The basic effect of an opening operation is reminiscent of erosion, since it tends to remove some of the foreground (bright) pixels at the edges. However, it is less destructive than erosion. The size and shape of the structuring element plays an important role in performing opening. The operation

FIGURE 29.10 Binary dilation by a  $3 \times 3$  flat structuring element.

preserves foreground regions that have a shape similar to its structuring element while erodes all other regions of foreground pixels. In mathematical terms opening can be written as:

$$A \circ B = (A \odot B) \oplus B \quad \text{or} \quad A \circ B = \cup[(B)_z \mid (B)_z \subseteq A] \tag{29.21}$$

While erosion can be used to eliminate small clumps of undesirable foreground pixels (e.g., “salt noise”) quite effectively, it has the disadvantage that it affects all foreground regions indiscriminately. Opening gets around this by performing both erosion and dilation on the image. The effect of opening can be visualized quite easily. Imagine taking the structuring element and sliding it inside each foreground region without changing its orientation. All foreground pixels that can be covered by the structuring element with the structuring element being entirely within the foreground region will be preserved. However, all foreground pixels which cannot be reached by the structuring element without parts of it moving out of the foreground region will be eroded away. After the opening has been carried out, the new boundaries of foreground regions will all be such that the structuring element fits inside them. Therefore, further openings with the same element have no effect, a property known as idempotence. The effect of an opening on a binary image using a  $3 \times 3$  flat structuring element is illustrated in Figure 29.11.

4. *White Top Hat Segmentation:* Many times gray scale images feature poor contrast. For example, in our case thermal imagery of human tissue has poor contrast around the vessels due to the thermal diffusion process. As a result, image thresholding yields very poor results. Top-hat segmentation is a morphological operation that corrects this problem. Top hat segmentation has two forms:

- White top hat segmentation
- Black top hat segmentation

The white top-hat segmentation process enhances the bright objects in the image, while the black top-hat segmentation enhances the dark objects. In our case, we are interested in enhancing the bright (hot) ridge like structures corresponding to the blood vessels. Therefore, we are interested only in the white top-hat segmentation process. Two methods have been introduced for performing the white top hat segmentation. The first one proposed in Reference 30 is based on image opening using a flat structuring element, while the second one proposed in Reference 31 uses H-dome transformation. We have adopted the first method where the image is first opened and then this opened image is subtracted from the original image. This gives only the peaks in the image and thus enhances the maxima. The step by step evolution of the original image toward the top-hat segmented image is shown in Figure 29.12. The simple functioning of top-hat transformation can be understood from the line profile plots in Figure 29.13.

## 29.4 Conclusion

We have outlined a novel approach to the problem of face recognition in thermal infrared. The cornerstones of the approach are a Bayesian face detection method followed by a physiological feature extractor. The face detector capitalizes upon the bimodal temperature distribution of human skin and typical indoor backgrounds. The physiological feature extractor delineates the facial vascular network based on a white top hat segmentation preceded by anisotropic diffusion (see Figure 29.14). These novel tools can be used

FIGURE 29.13 Image line profiles for (a) original, (b) opened, and (c) top-hat segmented image. The profiles were taken along the line shown in Figure 29.8.

FIGURE 29.14 (See color insert.) Segmented facial images annotated with the facial vascular network (yellow lines) as per the approach detailed in this chapter.

in combination with traditional classification methods to exploit the full potential of thermal infrared for face recognition — one of the fastest growing biometrics.

Noninvasive imaging techniques are emerging into the forefront of medical diagnostics and treatment monitoring. Both near- and mid-infrared imaging techniques have provided invaluable information in the clinical setting.

Near-infrared imaging in the spectrum of 700 to 1100 nm has been used to functionally monitor diseases processes including cancer and lymph node detection and optical biopsies. Spectroscopic imaging modalities have been shown to improve the diagnosis of tumors and add new knowledge about the physiological properties of the tumor and surrounding tissues. Particular emphasis should be placed on identifying markers that predict the risk of precancerous lesions progressing to invasive cancers, thereby providing new opportunities for cancer prevention. This might be accomplished through the use of markers as contrast agents for imaging using conventional techniques or through refinements of newer technologies such as MRI or PET scanning. The spectroscopic power of light, along with the revolution in molecular characterization of disease processes has created a huge potential for *in vivo* optical imaging and spectroscopy.

In the infrared thermal waveband, information about blood circulation, local metabolism, sweat gland malfunction, inflammation, and healing can be extracted. Infrared thermal imaging has been increasingly

used for detection of cancers. As this field evolves, abnormalities or changes in infrared images could be able to provide invaluable information to physicians caring for patients with a variety of disorders. The current status of modern infrared imaging is that of a first line supplement to both clinical exams and current imaging methods. Using infrared imaging to detect breast pathology is based on the principle that both metabolic and vascular activity in the tissue surrounding a new and developing tumor is usually higher than in normal tissue. Early cancer growth is dependent on increasing blood circulation by creating new blood vessels (angiogenesis). This process results in regional variations that can often be detected by infrared imaging.

Section 30.1 discusses near-infrared (NIR) imaging and its applications in imaging biological tissues. Infrared thermal imaging techniques, calibration and a current clinical trial of Kaposi's sarcoma are described in Section 30.2.

## 30.1 Near-Infrared Quantitative Imaging of Deep Tissue Structure

---

*In vivo* optical imaging has traditionally been limited to superficial tissue surfaces, directly or endoscopically accessible, and to tissues with a biological window (e.g., along the optical axis of the eye). These methods are based on geometric optics. Most tissues scatter light so strongly, however, that for geometric optics-based equipment to work, special techniques are needed to remove multiply scattered light (such as pinholes in confocal imaging or interferometry in optical coherence microscopies). Even with these special designs, high resolution optical imaging fails at depths of more than 1 mm below the tissue surface.

Collimated visible or infrared (IR) light impinging upon thick tissue is scattered many times in a distance of  $\sim 1$  mm, so the analysis of light-tissue interactions requires theories based on the diffusive nature of light propagation. In contrast to x-ray and Positron Emission Tomography (PET), a complex underlying theoretical picture is needed to describe photon paths as a function of scattering and absorption properties of the tissue.

Approximately a decade ago, a new field called "Photon Migration" was born that seeks to characterize the statistical physics of photon motion through turbid tissues. The goal has been to image macroscopic structures in 3D at greater depths within tissues and to provide reliable pathlength estimations for noninvasive spectral analysis of tissue changes. Although geometrical optics fails to describe light propagation under these conditions, the statistical physics of strong, multiply scattered light provides powerful approaches to macroscopic imaging and subsurface detection and characterization. Techniques using visible and NIR light offer a variety of functional imaging modalities, in addition to density imaging, while avoiding ionizing radiation hazards.

In Section 30.1.1, optical properties of biological tissue will be discussed. Section 30.1.2 is devoted to differing methods of measurements. Theoretical models for spectroscopy and imaging are discussed in Section 30.1.3. In Sections 30.1.4 and 30.1.5, two studies on breast imaging and the use of exogenous fluorescent markers will be presented as examples of NIR spectroscopy. Finally, the future direction of the field will be discussed in Section 30.1.6.

### 30.1.1 Optical Properties of Biological Tissue

The difficulty of tissue optics is to define optical coefficients of tissue physiology and quantify their changes to differentiate structures and functional status *in vivo*. Light-tissue interactions dictate the way that these parameters are defined. The two main approaches are the wave and particle descriptions of light propagation. The first leads to the use of Maxwell's equations, and therefore quantifies the spatially varying permittivity as a measurable quantity. For simplistic and historic reasons, the particle interpretation of light has been mostly used (see section on models of photon migration). In photon transport theory, one considers the behavior of discrete photons as they move through the tissue. This motion is characterized by absorption and scattering, and when interfaces (e.g., layers) are involved, refraction. The absorption

FIGURE 30.1 Absorption spectra of the three major components of tissue in the NIR region; oxy-hemoglobin, deoxy-hemoglobin and water.

coefficient,  $\mu_a$  ( $\text{mm}^{-1}$ ), represents the inverse mean pathlength of a photon before absorption.  $1/\mu_a$  is the distance in a medium where intensity is attenuated by a factor of  $1/e$  (Beer’s Lambert Law). Absorption in tissue is strongly wavelength dependent and is due to chromophores and water. Among the chromophores in tissue, the dominant component is the hemoglobin in blood. In Figure 30.1, hemoglobin absorption is divided into oxy- and deoxy-hemoglobin. As seen in this figure, in the visible range (600–700 nm), the blood absorption is relatively high compared to absorption in the NIR. By contrast, water absorption is low in the visible and NIR regions and increases rapidly above approximately 950 nm. Thus, for greatest penetration of light in tissue, wavelengths in the 650–950 nm spectrum are used most often. This region of the light spectrum is called “the therapeutic window.” One should note that different spectra of chromophores allow one to separate the contribution of varying functional species in tissue (e.g., quantification of oxy- and deoxy-hemoglobin to study tissue oxygenation).

Similarly, scattering is characterized by a coefficient,  $\mu_s$ , which is the inverse mean free path of photons between scattering events. The average size of the scattered photons in tissue, in proportion to the wavelength of the light, places the scattering in the Mie region. In the Mie region, a scattering event does not result in isotropic scattering angles [1,2]. Instead, the scattering in tissue is biased in the forward direction.

For example, by studying the development of neonatal skin, Saidi et al. [3] were able to show that the principal sources of anisotropic scattering in muscle are collagen fibers. The fibers were determined to have a mean diameter of  $2.2 \mu\text{m}$ . In addition to the Mie scattering from the fibers, there is isotropic Rayleigh scattering due to the presence of much smaller scatterers such as organelles in cells.

Anisotropic scattering is quantified in a coefficient,  $g$ , which is defined as the mean cosine of the scattering angle, where  $p(\theta)$  is the probability of a particular scattering angle,

$$g = \langle \cos(\theta) \rangle = \frac{\int_0^\pi p(\theta) \cos(\theta) \sin(\theta) d\theta}{\int_0^\pi p(\theta) \sin(\theta) d\theta} \tag{30.1}$$

For isotropic scattering,  $g = 0$ . For complete forward scattering,  $g = 1$ , and for complete back scattering,  $g = -1$ . In tissue,  $g$  is typically 0.7 to 0.98 [3–5].

Likewise, different tissue types have differing scattering properties which are also wavelength dependent. The scattering coefficients of many soft tissues have been measured at a variety of optical wavelengths, and are within the range 10 to  $100 \text{ mm}^{-1}$ . In comparison to absorption, however, scattering changes, as a function of wavelength, are more gradual and have smaller extremes. Abnormal tissues such as tumors, fibro-adenomas, and cysts all have scattering properties that are different from normal tissue [6,7]. Thus, the scattering coefficient of an inclusion may also be an important clue to disease diagnoses.

Theories of photon migration are often based on isotropic scattering. Therefore, one must find the appropriate scaling relationships that will allow use of an isotropic scattering model. For the case of diffusion-like models (e.g., see Reference 8), it has been shown that one may use an isotropic scattering model with a corrected scattering coefficient,  $\mu'_s$ , and obtain equivalent results where:

$$\mu'_s = \mu_s(1 - g) \quad (30.2)$$

The corrected scattering coefficient is smaller than the actual scattering which corresponds to a greater distance between isotropic scattering events than would occur with anisotropic scattering. For this reason,  $\mu'_s$  is typically called the transport-corrected scattering coefficient.

There are instances in which the spectroscopic signatures will not be sufficient for detection of disease. This can occur when the specific disease results in only very small changes to the tissue's scattering and absorption properties, or when the scattering and absorption properties are not unique to the disease. Although it is not clear what the limits of detectability are in relationship to diseased tissue properties, it is clear that there will be cases for which optical techniques based on elastic absorption are inadequate. In such cases, another source of optical contrast, such as fluorescence, will be required to detect and locate the disease. Presence of fluorescent molecules in tissues can provide useful contrast mechanisms. Concentration of these endogenous fluorophores in the body can be related to functional and metabolic activities, and therefore to the disease processes. For example, the concentrations of fluorescent molecules such as collagen and NADH have been used to differentiate between normal and abnormal tissue [9].

Advances in the molecular biology of disease processes, new immunohistopathological techniques, and the development of fluorescently-labeled cell surface markers have led to a revolution in specific molecular diagnosis of disease by histopathology, as well as in research on molecular origins of disease processes (e.g., using fluorescence microscopy in cell biology). As a result, an exceptional level of specificity is now possible due to the advances in the design of exogenous markers. Molecules can now be tailor-made to bind only to specific receptor sites in the body. These receptor sites may be antibodies or other biologically interesting molecules. Fluorophores may be bound to these engineered molecules and injected into the body, where they will preferentially concentrate at specific sites of interest [10,11].

Furthermore, fluorescence may be used as a probe to measure environmental conditions in a particular locality by capitalizing on changes in fluorophore lifetimes [12,13]. Each fluorophore has a characteristic lifetime that quantifies the probability of a specific time delay between fluorophore excitation and emission. In practice, this lifetime may be modified by specific environmental factors such as temperature, pH, and concentrations of substances such as oxygen. In these cases, it is possible to quantify local concentrations of specific substances or specific environmental conditions by measuring the lifetime of fluorophores at the site. Whereas conventional fluorescence imaging is very sensitive to non-uniform fluorophore transport and distribution (e.g., blood does not transport molecules equally to all parts of the body), fluorescence lifetime imaging is insensitive to transport non-uniformity as long as a detectable quantity of fluorophores is present in the site of interest. Throughout the following sections, experimental techniques and differing models used to quantify these sources of optical contrast will be presented.

### 30.1.2 Measurable Quantities and Experimental Techniques

Three classes of measurable quantities prove to be of interest in transforming results of remote sensing measurements in tissue into useful physical information. The first is the spatial distribution of light or the intensity profile generated by photons re-emitted through a surface and measured as a function of the radial distance from the source and the detector when the medium is continually irradiated by a point source (often a laser). This type of measurement is called continuous wave (CW). The intensity, nominally, does not vary in time. The second class is the temporal response to a very short pulse ( $\sim$ picosecond) of photons impinging on the surface of the tissue. This technique is called time-resolved and the temporal response is known as the time-of-flight (TOF). The third class is the frequency-domain technique in which an intensity-modulated laser beam illuminates the tissue. In this case, the measured outputs are

the AC modulation amplitude and the phase shift of the detected signal. These techniques could be implemented in geometries with different arrangements of source(s) and detector(s); (a) in the reflection mode, source(s) and detector(s) are placed at the same side of the tissue; (b) in the transmission mode, source(s) and detector(s) are located on opposite sides of the tissue. In the latter, the source(s) and detector(s) can move in tandem while scanning the tissue surface and detectors with lateral offsets also can be used; and (c) tomographic sampling often uses multiple sources and detectors placed around the circumference of the target tissue.

For CW measurements, the instrumentation is simple and requires only a set of light sources and detectors. In this technique, the only measurable quantity is the intensity of light, and, due to multiple scattering, strong pathlength dispersion occurs which results in a loss of localization and resolution. Hence, this technique is widely used for spectroscopic measurements of bulk tissue properties in which the tissue is considered to be homogeneous [14,15]. However, CW techniques for imaging abnormal targets that use only the coherent portion of light, and thereby reject photons with long paths, have also been investigated. Using the transillumination geometry, collimated detection is used to isolate un-scattered photons [16–18]. Spatial filtering has been proposed which employs a lens to produce the Fourier spectrum of the spatial distribution of light from which the high-order frequencies are removed. The resulting image is formed using only the photons with angles close to normal [19]. Polarization discrimination has been used to select those photons which undergo few scattering events and therefore preserve a fraction of their initial polarization state, as opposed to those photons which experience multiple scattering resulting in complete randomization of their initial polarization state [20]. Several investigators have used heterodyne detection which involves measuring the beat frequency generated by the spatial and temporal combination of a light beam and a frequency modulated reference beam. Constructive interference occurs only for the coherent portion of the light [20–22]. However, the potential of direct imaging using CW techniques in very thick tissue (e.g., breast) has not been established. On the other hand, use of models of photon migration implemented in inverse method based on backprojection techniques has shown promising results. For example, Phillips Medical has used 256 optical fibers placed at the periphery of a white conical shaped vessel. The area of interest, in this case the breast, is suspended in the vessel, and surrounded by a matching fluid. Three CW laser diodes sequentially illuminate the breast using one fiber. The detection is done simultaneously by 255 fibers. It is now clear that CW imaging cannot provide direct images with clinically acceptable resolution in thick tissue. Attempts are underway to devise inverse algorithms to separate the effects of scattering and absorption and therefore use this technique for quantitative spectroscopy as proposed by Phillips [23]. However, until now, clinical application of CW techniques in imaging has been limited by the mixture of scattering and absorption of light in the detected signal. To overcome this problem, time-dependent measurement techniques have been investigated.

Time-domain techniques involve the temporal resolution of photons traveling inside the tissue. The basic idea is that photons with smaller pathlengths are those that arrive earlier to the detector. In order to discriminate between un-scattered or less scattered light and the majority of the photons, which experience a large number of multiple scattering, subnanosecond resolution is needed. This short time gating of an imaging system requires the use of a variety of techniques involving ultra-fast phenomena and/or fast detection systems. Ultra-fast shuttering is performed using the Kerr effect. The birefringence in the Kerr cell, placed between two crossed polarizers, is induced using very short pulses. Transmitted light through the Kerr cell is recorded, and temporal resolution of a few picoseconds is achieved [19]. When an impulse of light ( $\sim$ picoseconds or hundreds of femtoseconds) is launched at the tissue surface, the whole temporal distribution of photon intensity can be recorded by a streak camera. The streak camera can achieve temporal resolution on the order of few picoseconds up to several nanoseconds detection time. This detection system has been widely used to assess the performance of breast imaging and neonatal brain activity [24,25]. The time of flight recorded by the streak camera is the convolution of the pulsed laser source (in practice with a finite width) and the actual Temporal Point Spread Function (TPSF) of the diffuse photons. Instead of using very short pulse lasers (e.g., Ti-Sapphire lasers), the advent of pulse diode lasers with relatively larger pulse widths (100 to 400 psec) have reduced the cost of time-domain imaging. However, deconvolution of the incoming pulse and the detected TPSF have been a

greater issue. Along with diode laser sources, several groups have also used time-correlated single photon counting with photomultipliers for recording the TPSF [26,27]. Fast time gating is also obtained by using Stimulated Raman Scattering. This phenomenon is a nonlinear Raman interaction in some materials such as hydrogen gas involving the amplification of photons with Stokes shift by a higher energy pump beam. The system operates by amplifying only the earliest arriving photons [28]. Less widely used techniques such as second-harmonic generation [29], parametric amplification [30] and a variety of others have been proposed for time-domain (see an excellent review in Reference 31).

For frequency-domain measurements, the requirement is to measure the DC amplitude, the AC amplitude, and the phase shift of the photon density wave. For this purpose a CW light source is modulated with a given frequency ( $\sim 100$  MHz). Lock-in Amplifiers and phase sensitive CCD camera have been used to record the amplitude and phase [32,33]. Multiple sources at different wavelengths can be modulated with a single frequency or multiple frequencies [6,34]. In the latter case a network analyzer is used to produce modulation swept from several hundreds of MHz to up to 1 GHz.

### 30.1.3 Models of Photon Migration in Tissue

Photon Migration theories in biomedical optics have been borrowed from other fields such as astrophysics, atmospheric science, and specifically from nuclear reactor engineering [35,36]. The common properties of these physical media and biological tissues are their characterization by elements of randomness in both space and time. Because of many difficulties surrounding the development of a theory based on a detailed picture of the microscopic processes involved in the interaction of light and matter, investigations are often based on statistical theories. These can take a variety of forms, ranging from quite detailed multiple-scattering theories [36] to transport theory [37]. However, the most widely used theory is the time-dependent diffusion approximation to the transport equation:

$$\vec{\nabla} \cdot (D\vec{\nabla}\Phi(\vec{r}, t)) - \mu_a\Phi(\vec{r}, t) = \frac{1}{c} \frac{\partial\Phi(\vec{r}, t)}{\partial t} - S(\vec{r}, t) \quad (30.3)$$

where  $\vec{r}$  and  $t$  are spatial and temporal variables,  $c$  is the speed of light in tissue, and  $D$  is the diffusion coefficient related to the absorption and scattering coefficients as follows:

$$D = \frac{1}{3[\mu_a + \mu'_s]} \quad (30.4)$$

The quantity  $\Phi(\vec{r}, t)$  is called the fluence, defined as the power incident on an infinitesimal volume element divided by its area. Note that the equation does not incorporate any angular dependence, therefore assuming an isotropic scattering. However, for the use of the diffusion theory for anisotropic scattering, the diffusion coefficient is expressed in terms of the transport-corrected scattering coefficient.  $S(\vec{r}, t)$  is the source term. The gradient of fluence,  $J(\vec{r}, t)$ , at the tissue surface is the measured flux of photons by the detector:

$$J(\vec{r}, t) = -D\vec{\nabla}\Phi(\vec{r}, t) \quad (30.5)$$

For CW measurements, the time-dependence of the flux vanishes, and the source term can be seen as the power impinging in its area. For time-resolved measurements, the source term is a Dirac delta function describing a very short photon impulse. Equation 30.3 has been solved analytically for different types of measurements such as reflection and transmission modes assuming that the optical properties remain invariant through the tissue. To incorporate the finite boundaries, the method of images has been used. In the simplest case, the boundary has been assumed to be perfectly absorbing which does not take into account the difference between indices of refraction at the tissue-air interface. For semi-infinite and transillumination geometries, a set of theoretical expressions has been obtained for time-resolved measurements [38].

The diffusion approximation equation in the frequency-domain is the Fourier transformation of the time-domain with respect to time. Fourier transformation applied to the time-dependent diffusion equation leads to a new equation:

$$\vec{\nabla} \cdot (D\vec{\nabla}\Phi(\vec{r}, \omega)) - \left[ \mu_a + \frac{i\omega}{c} \right] \Phi(\vec{r}, \omega) + S(\vec{r}, \omega) = 0 \quad (30.6)$$

Here the time variable is replaced by the frequency  $\omega$ . This frequency is the modulation angular frequency of the source. In this model, the fluence can be seen as a complex number describing the amplitude and phase of the photon density wave, dumped with a DC component:

$$\Phi(\vec{r}, \omega) = \Phi_{AC}(\vec{r}, \omega) + \Phi_{DC}(\vec{r}, 0) = I_{AC} \exp(i\theta) + \Phi_{DC}(\vec{r}, 0) \quad (30.7)$$

In the RHS of Equation 30.7, the quantity  $\theta$  is the phase shift of the diffusing wave. For a nonabsorbing medium, its wavelength is:

$$\lambda = 2\pi \sqrt{\frac{2c}{3\mu'_s\omega}} \quad (30.8)$$

Likewise in the time-domain, Equation 30.3 has an analytical solution for the case that the tissue is considered homogeneous. The analytical solution permits one to deduce the optical properties in a spectroscopic setting.

For imaging, where the goal is to distinguish between structures in tissue, the diffusion coefficient and the absorption coefficient in Equation 30.3 and Equation 30.6 become spatial-dependent and are replaced by  $D(r)$  and  $\mu_a(r)$ . For the cases that an abnormal region is embedded in otherwise homogeneous tissue, perturbation methods based on Born approximation or Rytov approximation have been used (see excellent review in Reference 39). However, for the cases that the goal is to reconstruct the spectroscopic signatures inside the tissue, no analytical solution exists. For these cases, inverse algorithms are devised to map the spatially varying optical properties. Numerical methods such as finite-element or finite-difference methods have been used to reconstruct images of breast, brain, and muscle [40–42]. Furthermore, in those cases that structural heterogeneity exists, a priori information from other image modalities such as MRI can be used. An example is given in Figure 30.2. Combining MRI and NIR imaging, rat cranium functional imaging during changes in inhaled oxygen concentration was studied [43]. Figure 30.2a,b correspond to the MRI image and the corresponding constructed finite-element mesh. Figure 30.2c,d correspond to the oxygen map of the brain with and without incorporation of MRI geometry and constraints.

The use of MRI images has improved dramatically the resolution of the oxygen map. The use of optical functional imaging in conjunction with other imaging modalities has opened new possibilities in imaging and treating diseases at the bedside.

The second theoretical framework used in tissue optics is the random walk theory (RWT) on a lattice developed at the National Institutes of Health [44,45] and historically precedes the use of the diffusion approximation theory. It has been shown that RWT may be used to derive an analytical solution for the distribution of photon path-lengths in turbid media such as tissue [44]. RWT models the diffusion-like motion of photons in turbid media in a probabilistic manner. Using RWT, an expression may be derived for the probability of a photon arriving at any point and time given a specific starting point and time.

Tissue may be modeled as a 3D cubic lattice containing a finite inclusion, or region of interest, as shown in Figure 30.3. The medium has an absorbing boundary corresponding to the tissue surface, and the lattice spacing is proportional to the mean photon scattering distance,  $1/\mu'_s$ . The behavior of photons in the RWT model is described by three dimensionless parameters,  $\rho$ ,  $n$ ,  $\mu$ , which are respectively the radial distance, the number of steps, and the probability of absorption per lattice step. In the RWT model, photons may move to one of the six nearest neighboring lattice points, each with probability 1/6. If the number of steps,  $n$ , taken by a photon traveling between two points on the lattice is known, then the length of the photon's path is also known.

**FIGURE 30.2** (See color inset following page 29-16.) Functional imaging of rat cranium during changes in inhaled oxygen concentration: (a) MRI image; (b) creation of the mesh to distinguish different compartments in the brain; (c) map of hemoglobin concentration and oxygen saturation of the rat brain without structural constraints from MRI; (d) same as (c) with structural constraints including tissue heterogeneity. In (c) and (d) the rows from top correspond to 13, 8, and 0% (after death) oxygen inhaled. (Courtesy of Dartmouth College.)

**FIGURE 30.3** 2D random walk lattice showing representative photon paths from an emitter to a specific site and then to a detector.

Random walk theory is useful in predicting the probability distribution of photon path lengths over distances of at least five mean photon scattering distances. The derivation of these probability distributions is described in papers [44,45]. For simplicity in this derivation, the tissue–air interface is considered to be perfectly absorbing; a photon arriving at this interface is counted as arriving at a detector on the tissue surface. The derivation uses the Central Limit Theorem and a Gaussian distribution around lattice points to obtain a closed-form solution that is independent of the lattice structure.

The dimensionless RWT parameters,  $\rho$ ,  $n$ , and  $\mu$ , described above, may be transformed to actual parameters, in part, by using time,  $t$ , the speed of light in tissue,  $c$ , and distance traveled,  $r$ , as follows:

$$\rho \rightarrow \frac{r\mu'_s}{\sqrt{2}}, \quad n \rightarrow \mu'_s ct, \quad \mu \rightarrow \frac{\mu_a}{\mu'_s} \tag{30.9}$$

As stated previously, scattering in tissue is highly anisotropic. Therefore, one must find the appropriate scaling relationships that will allow the use of an isotropic scattering model such as RWT. Like diffusion theory, for RWT [46], it has been shown that one may use an isotropic scattering model with a corrected scattering coefficient,  $\mu'_s$ , and obtain equivalent results. The corrected scattering coefficient is smaller than the actual scattering that corresponds to a greater distance between isotropic scattering events than would occur with anisotropic scattering. RWT has been used to show how one would transition from the use of  $\mu_s$  to  $\mu'_s$  as the distance under consideration increases [47].

As an example, for a homogeneous slab into which a photon has been inserted, the probability,  $P$ , of a photon arriving at a point  $\rho$  after  $n$  steps is [48]:

$$P(n, \rho) = \frac{\sqrt{3}}{2} \left[ \frac{1}{2\pi(n-2)} \right]^{3/2} e^{-3\rho^2/2(n-2)} \sum_{k=-\infty}^{\infty} \left[ e^{-3[(2k+1)L-2]^2/2(n-2)} - e^{-3[(2k+1)L]^2/2(n-2)} \right] e^{-n\mu} \tag{30.10}$$

where  $L$  is the thickness of the slab. The method of images has been used to take into account the two boundaries of the slab. Plotting Equation 30.10 yields a photon arrival curve as shown in Figure 30.4; Monte Carlo simulation data are overlaid. In the next two sections the use of RWT for imaging will be presented.

### 30.1.4 RWT Applied to Quantitative Spectroscopy of the Breast

One important and yet extremely challenging areas to apply diffuse optical imaging of deep tissues is the human breast (see review article of Hawrysz and Sevick-Muraca [49]). It is clear that any new imaging

**FIGURE 30.4** RWT prediction and Monte Carlo simulation results for transillumination of a 15-mm thick slab with scattering 1/mm and 109 photons.

or spectroscopic modalities that can improve the diagnosis of breast tumors or can add new knowledge about the physiological properties of the breast and surrounding tissues will have a great significance in medicine.

Conventional transillumination using continuous wave (CW) light was used for breast screening several decades ago [50]. However, because of the high scattering properties of tissue, this method resulted in poor resolution. In the late 1980s, time-resolved imaging techniques were proposed to enhance spatial resolution by detecting photons with very short time-of-flight within the tissue. In this technique, a very short pulse, of  $\sim$ picosecond duration, impinges upon the tissue. Photons experience dispersion in their pathlengths, resulting in temporal dispersion in their time-of-flight (TOF).

To evaluate the performance of time-resolved transillumination techniques, RWT on a lattice was used. The analysis of breast transillumination was based on the calculation of the point spread function (PSF) of time resolved photons as they visit differing sites at different planes inside a finite slab of thickness  $L$ . The PSF [51], is defined as the probability that a photon inserted into the tissue visits a given site, is detected at the  $n$ th step (i.e., a given time), and has the following rather complicated analytical expression:

$$W_n(\mathbf{s}, \mathbf{r}, \mathbf{r}_0) = \sum_{l=0}^n p_l(\mathbf{r}, \mathbf{s}) p_{n-l}(\mathbf{s}, \mathbf{r}_0) = \frac{9}{16\pi^{5/2} n^{3/2}} \sum_{k=-\infty}^{\infty} \sum_{m=-\infty}^{\infty} \{F_n[\alpha_+(k), \beta_+(m, p)] \quad (30.11)$$

$$+ F_n[\alpha_-(k), \beta_-(m, p)] - F_n[\alpha_+(k), \beta_-(m, p)] - F_n[\alpha_-(k), \beta_+(m, p)]\}$$

$$F_n(a, b) = \left(\frac{1}{a} + \frac{1}{b}\right) \exp\left[-\frac{(a+b)^2}{n}\right] \quad (30.12)$$

$$\alpha_{\pm}(k) = \left\{\frac{3}{2}[s_1^2 + (s_3 + 2kN \pm 1)^2]\right\}^{\frac{1}{2}} \quad (30.13)$$

$$\beta_{\pm}(k, \rho) = \left\{\frac{3}{2}[(\rho - s_1)^2 + (N - s_3 + 2kN \pm 1)^2]\right\}^{\frac{1}{2}} \quad (30.14)$$

where  $N = (\mu'_s/\sqrt{2}) + 1$  is dimensionless RWT thickness of the slabs,  $\bar{s}(s_1, s_2, s_3)$  are the dimensionless coordinates (see Equation 30.9) of any location for which the PSF is calculated. Evaluation of time-resolved imaging showed that strong scattering properties of tissues prevent direct imaging of abnormalities [52]. Hence, devising theoretical constructs to separate the effects of the scattering from the absorption was proposed, thus allowing one to map the optical coefficients as spectroscopic signatures of an abnormal tissue embedded in thick, otherwise normal tissue. In this method, accurate quantification of the size and optical properties of the target becomes a critical requirement for the use of optical imaging at the bedside. RWT on a lattice has been used to analyze the time-dependent contrast observed in time-resolved transillumination experiments and deduce the size and optical properties of the target and the surrounding tissue from these contrasts. For the theoretical construction of contrast functions, two quantities are needed. First, the set of functions [51] defined previously. Second, the set of functions [53] defined as the probability that a photon is detected at the  $n$ th step (i.e., time) in a homogeneous medium (Equation 30.10)[48].

To relate the contrast of the light intensity to the optical properties and location of abnormal targets in the tissue, one can take advantage of some features of the theoretical framework. One feature is that the early time response is most dependent on scattering perturbations, whereas the late time behavior is most dependent on absorptive perturbations, thus allowing one to separate the influence of scattering and absorption perturbations on the observed image contrast. Increased scattering in the abnormal target is modeled as a time delay. Moreover, it was shown that the scattering contrast is proportional to the time-derivative of the PSF,  $dW_n/dn$ , divided by  $P_n$  [53]. The second interesting feature in RWT methodology

assumes that the contrast from scattering inside the inclusion is proportional to the cross-section of the target (in the  $z$  direction) [51,53], instead of depending on its volume as modeled in the perturbation analysis [54].

Several research groups intend to implement their theoretical expressions into general inverse algorithms for optical tomography, that is, to reconstruct three-dimensional maps of spatial distributions of tissue optical characteristics [49], and thereby quantify optical characteristics, positions and sizes of abnormalities. Unlike these approaches, method is a multi-step analysis of the collected data. From images observed at differing flight times, we construct the time-dependent contrast functions, fit our theoretical expressions, and compute the optical properties of the background, and those of the abnormality along with its size. The outline of data analysis is given in Reference 55.

By utilizing the method for different wavelengths, one can obtain diagnostic information (e.g., estimates of blood oxygenation of the tumor) for corresponding absorption coefficients that no other imaging modality can provide directly. Several research groups have already successfully used multi-wavelength measurements using frequency-domain techniques, to calculate physiological parameters (oxygenation, lipid, water) of breast tumors (diagnosed with other modalities) and normal tissue [56].

Researchers at Physikalisch-Technische-Bundesanstalt (PTB) of Berlin have designed a clinically practical optical imaging system, capable of implementing time-resolved *in vivo* measurements on the human breast [27]. The breast is slightly compressed between two plates. A scan of the whole breast takes but a few minutes and can be done in mediolateral and craniocaudal geometries. The first goal is to quantify the optical parameters at several wavelengths and thereby estimate blood oxygen saturation of the tumor and surrounding tissue under the usual assumption that the chromophores contributing to absorption are oxy- and deoxy-hemoglobin and water. As an example, two sets of data, obtained at two wavelengths ( $\lambda = 670$  and  $785$  nm), for a patient (84-year-old) with invasive ductal carcinoma, were analyzed. Though the images exhibit poor resolution, the tumor can be easily seen in the optical image shown in Figure 30.5a. In this figure, the image is obtained from reciprocal values of the total integrals of the distributions of times of flight of photons, normalized to a selected “bulk” area. The tumor center is located at  $x = -5$ ,  $y = 0.25$  mm.

The best spatial resolution is observed, as expected, for shorter time-delays allowing one to determine the position of the tumor center on the 2-D image (transverse coordinates) with accuracy  $\sim 2.5$  mm. After preliminary data processing that includes filtering and deconvolution of the raw time-resolved data, we created linear contrast scans passing through the tumor center and analyzed these scans, using our algorithm. It is striking that one observes similar linear dependence of the contrast amplitude on the derivative of PSF ( $\lambda = 670$  nm), as expected in the model (see Figure 30.5b). The slope of this linear dependence was used, to estimate the amplitude of the scattering perturbation [55].

**FIGURE 30.5** (a) 2-D optical image of the breast with the tumor. (Courtesy of Physikalisch-Technische-Bundesanstalt, Berlin.) (b) Contrast obtained from linear scan through the tumor plotted vs. the derivative of PSF. From the linear regression the scattering coefficient of the tumor is deduced.

**TABLE 30.1** Optical Parameters of Tumor and Background Breast Tissue

Unknown coefficients	Reconstructed values ( $\text{mm}^{-1}$ )	
	$\lambda = 670 \text{ nm}$	$\lambda = 785 \text{ nm}$
Absorption (background)	$0.0029^{-1}$	$0.0024^{-1}$
Scattering (background)	$1.20^{-1}$	$1.10^{-1}$
Absorption (tumor)	$0.0071^{-1}$	$0.0042^{-1}$
Scattering (tumor)	$1.76^{-1}$	$1.6^{-1}$

Dimensions and values of optical characteristics of the tumor and surrounding tissues were then reconstructed for both wavelengths. Results show that the tumor had larger absorption and scattering than the background. Estimated parameters are presented in Table 30.1.

Both absorption and scattering coefficients of the tumor and background all proved to be larger at the red wavelength (670 nm). Comparison of the absorption in the red and near infrared range is used to estimate blood oxygen saturation of the tumor and background tissue. Preliminary results of the analysis gave evidence that the tumor tissue is in a slightly deoxygenated state with higher blood volume, compared to surrounding tissue.

The spectroscopic power of optical imaging, along with the ability to quantify physiological parameters of human breast, have opened a new opportunity for assessing metabolic and physiological activities of the human breast during treatment.

### 30.1.5 Quantitative Fluorescence Imaging and Spectroscopy

As mentioned in Section 30.1.1, advances in the molecular biology of disease processes, new immunohistochemical techniques, and the development of specific fluorescently-labeled cell surface markers have led a revolution in research on the molecular origins of disease processes. On the other hand, reliable, sensitive, and specific, non-invasive techniques are needed for *in vivo* determinations of abnormalities within tissue. If successfully developed, noninvasive “optical biopsies” may replace conventional surgical biopsies and provide the advantages of smaller sampling errors, reduction in cost and time for diagnosis resulting in easier integration of diagnosis and therapy by following the progression of disease or regression in response to therapy. Clinically practical fluorescence imaging techniques must meet several requirements. First, the pathology under investigation must lie above a depth where the attenuation of the signal results in a poor signal-to-noise ratio and resolvability. Second, the specificity of the marker must be high enough that one can clearly distinguish between normal and abnormal lesions. Finally, one must have a robust image reconstruction algorithm which enables one to quantify the fluorophore concentration at a given depth.

The choices of projects in this area of research are dictated by the importance of the problem, and the impact of the solution on health care. Below, the rationale of two projects, are described that National Institutes of Health are pursuing.

Sjogren’s Syndrome (SS) has been chosen as an appropriate test case for developing a noninvasive optical biopsy based on 3-D localization of exogenous specific fluorescent labels. SS is an autoimmune disease affecting minor salivary glands which are near (0.5 to 3.0 mm below) the oral mucosal surface [57]. Therefore the target pathology is relatively accessible to noninvasive optical imaging. The hydraulic conductivity of the oral mucosa is relatively high, which along with the relatively superficial location of the minor salivary glands, makes topical application and significant labeling of diseased glands with large fluorescent molecules easy to accomplish. Fluorescence ligands (e.g., fluorescent antibodies specific to  $\text{CD4}^+$  T cell-activated lymphocytes infiltrating the salivary glands) are expected to bind specifically to the atypical cells in the tissue, providing high contrast and a quantitative relationship to their concentration (and therefore to the stage of the disease process). The major symptoms (dry eyes and dry mouth due to

decreased tear and saliva secretion) are the result of progressive immune-mediated dysfunction of the lacrimal and salivary glands. Currently, diagnosis is made by excisional biopsies of the minor salivary glands in the lower lip. This exam, though considered the best criterion for diagnosis, involves a surgical procedure under local anesthesia followed by postoperative discomfort (swelling, pain) and frequently a temporary loss of sensation at the lower lip biopsy site. Additionally, biopsy is inherently subject to sampling errors and the preparation of histopathological slides is time consuming, complicated, expensive, and requires the skills of several professionals (dentist, pathologist, and laboratory technician). Thus, there is a clear need for a noninvasive diagnostic procedure which reflects the underlying gland pathology and has good specificity. A quantitative, noninvasive assay would also allow repetition of the test to monitor disease progression and the effect of treatment. However, the quantification of fluorophore concentration within the tissue from surface images requires determining the intensities of different fluorophore sources, as a function of depth and transverse distance and predicting the 3-D distribution of fluorophores within the tissue from a series of images [58].

The second project involves the lymphatic imaging-sentinel node detection. The stage of cancer at initial diagnosis often defines prognosis and determines treatment options. As part of the staging procedure of melanoma and breast cancer, multiple lymph nodes are surgically removed from the primary lymphatic draining site and examined histologically for the presence of malignant cells. Because it is not obvious which nodes to remove at the time of resection of the primary tumor, standard practice involves dissection of as many lymph nodes as feasible. Since such extensive removal of lymphatic tissue frequently results in compromised lymphatic drainage in the examined axilla, alternatives have been sought to define the stage at the time of primary resection. A recent advance in lymph node interrogation has been the localization and removal of the "sentinel" node. Although there are multiple lymphatic channels available for trafficking from the primary tumor, the assumption was made that the anatomic location of the primary tumor in a given individual drains into lymphatic channels in an orderly and reproducible fashion. If that is in fact the case, then there is a pattern by which lymphatic drainage occurs. Thus, it would be expected that malignant cells from a primary tumor site would course from the nearest and possibly most superficial node into deeper and more distant lymphatic channels to ultimately arrive in the thoracic duct, whereupon malignant cells would gain access to venous circulation. The sentinel node is defined as the first drainage node in a network of nodes that drain the primary cancer. Considerable evidence has accrued validating the clinical utility of staging breast cancer by locating and removing the sentinel node at the time of resection of the primary tumor. Currently, the primary tumor is injected with a radionuclide one day prior to removal of the primary tumor. Then, just before surgery, it is injected with visible dye. The surgeon localizes crudely the location of the sentinel node using a hand-held radionuclide detector, followed by a search for visible concentrations of the injected dye. The method requires expensive equipment and also presents the patient and hospital personnel with the risk of exposure to ionizing radiation. As an alternative to the radionuclide, we are investigating the use of IR-dependent fluorescent detection methods to determine the location of sentinel node(s).

For *in vivo* fluorescent imaging, a complicating factor is the strong attenuation of light as it passes through tissue. This attenuation deteriorates the signal-to-noise ratio of detected photons. Fortunately, development of fluorescent dyes (such as porphyrin and cyanine) that excite and re-emit in the "biological window" at NIR wavelengths, where scattering and absorption coefficients are relatively low, have provided new possibilities for deep fluorescence imaging in tissue. The theoretical complication occurs at depths greater than 1 mm where photons in most tissues enter a diffusion-like state with a large dispersion in their path-lengths. Indeed, the fluorescent intensity of light detected from deep tissue structures depends not only on the location, size, concentration, and intrinsic characteristics (e.g., lifetime, quantum efficiency) of the fluorophores, but also on the scattering and absorption coefficients of the tissue at both the excitation and emission wavelengths. Hence, in order to extract intrinsic characteristics of fluorophores within tissue, it is necessary to describe the statistics of photon pathlengths which depend on all these differing parameters.

Obviously, the modeling of fluorescent light propagation depends on the kinds of experiments that one plans to perform. For example, for frequency-domain measurements, Patterson and Pogue [59]

used the diffusion approximation of the transport equation to express their results in terms of a product of two Green's function propagators multiplied by a term that describes the probability of emission of a fluorescent photon at the site. One Green's function describes the movement of an incident photon to the fluorophore, and the other describes movement of the emitted photon to the detector. In this representation, the amount of light emitted at the site of the fluorophore is directly proportional to the total amount of light impinging on the fluorophore, with no account for the variability in the number of visits by a photon before an exciting transformation. Since a transformation on an early visit to the site precludes a transformation on all later visits, this results in an overestimation of the number of photons which have a fluorescence transformation at a particular site. This overestimation is important when fluorescent absorption properties are spatially inhomogeneous and largest at later arrival times. RWT has been used to allow for this spatial inhomogeneity by introducing the multiple-passage probabilities concept, thus rendering the model more physically plausible [60]. Another incentive to devise a general theory of diffuse fluorescence photon migration is the capability to quantify local changes in fluorescence lifetime. By selecting fluorophore probes with known lifetime dependence on specific environmental variables, lifetime imaging enables one to localize and quantify such metabolic parameters as temperature and pH, as well as changes in local molecular concentrations *in vivo*.

In the probabilistic RWT model, the description of a photon path may be divided into three parts: the path from the photon source to a localized, fluorescing target; the interaction of the photon with the fluorophore; and finally, the path of the fluorescently emitted photon to a detector. Each part of the photon path may be described by a probability: first, the probability that an incident photon will arrive at the fluorophore site; second, the probability that the photon has a reactive encounter with the fluorophore and the corresponding photon transit delay, which is dependent on the lifetime of the fluorophore and the probability of the fluorophore emitting a photon; and third, the probability that the photon emitted by the fluorophore travels from the reaction site to the detector. Each of these three sequences is governed by a stochastic process. The mathematical description of the three processes is extremely complicated. The complete solution for the probability of fluorescence photon arrival at the detector is [61]:

$$\hat{\gamma}(r, s, r_0) = [\eta \Phi \hat{p}'_{\xi}(r | s) \hat{p}_{\xi}(s | r_0)] \times \left[ \langle \Delta n \rangle (1 - \eta) [\exp(\xi) - 1] + \{ \eta \langle \Delta n \rangle [\exp(\xi) - 1] + 1 \} \left\{ 1 + \left[ (1/8)(3/\pi)^{3/2} \sum_{j=1}^{\infty} \exp(-2j\xi) / j^{3/2} \right] \right\} \right]^{-1} \quad (30.15)$$

where  $\eta$  is the probability of fluorescent absorption of an excitation wavelength photon,  $\Phi$  is the quantum efficiency of the fluorophore which is the probability that an excited fluorophore will emit a photon at the emission wavelength,  $\langle \Delta n \rangle$  is the mean number of steps the photon would have taken had the photon not been exciting the fluorophore (which corresponds to the fluorophore lifetime in random walk parameters) and  $\xi$  is a transform variable corresponding to the discrete analog of the Laplace transform and may be considered analogous to frequency. The probability of a photon going from the excitation source to the fluorophore site is  $\hat{p}_{\xi}(s | r_0)$ , and the probability of a fluorescent photon going from the fluorophore site to the detector is  $\hat{p}'_{\xi}(r | s)$ ; the prime indicates that the wavelength of the photon has changed and therefore the optical properties of the tissue may be different. In practice, this solution is difficult to work with, so some simplifying assumptions are desired. With some simplification the result in the frequency domain is:

$$\hat{\gamma}(r, s, r_0) = \eta \Phi \{ \hat{p}'_{\xi}(r | s) \hat{p}_{\xi}(s | r_0) - \xi \langle \Delta n \rangle \hat{p}'_{\xi}(r | s) \hat{p}_{\xi}(s | r_0) \} \quad (30.16)$$

The inverse Laplace transform of this equation gives the diffuse fluorescent intensity in the time-domain, and the integral of the latter over time leads to CW measurements. The accuracy of such cumbersome equations is tested in well-defined phantoms and fluorophores embedded in *ex vivo* tissue. In Figure 30.6, a line scan of fluorescent intensity collected from 500  $\mu\text{m}^3$  fluorescent dye (Molecular Probe, far red microspheres: 690 nm excitation; 720 nm emission), embedded in 10.4 mm porcine tissue

**FIGURE 30.6** Intensity scan of a fluorophore 10.4 mm below the tissue surface.

with a lot of heterogeneity (e.g., fat), are presented. The dashed line is the corresponding RWT fit. The inverse algorithm written in C++ was able to construct the depth of the fluorophore with 100% accuracy. Knowing the heterogeneity of the tissue (seen in the intensity profile) this method presents huge potential to interrogate tissue structures deeply embedded in tissue for which specific fluorescent labeling such as antibodies for cell surfaces exists.

### 30.1.6 Future Directions

A clinically useful optical imaging device requires multidisciplinary and multi-step approaches. At the desk, one devises quantitative theories, and develop methodologies applicable to *in vivo* quantitative tissue spectroscopy and tomographic imaging in different imaging geometries (i.e., transmission or reflection), different types of measurements (e.g., steady-state or time-resolved). Effects of different optical sources of contrast such as endogenous or exogenous fluorescent labels, variations in absorption (e.g., hemoglobin or chromophore concentration) and scattering should be incorporated in the model. At the bench, one designs and conducts experiments on tissue-like phantoms and runs computer simulations to validate the theoretical findings. If successful, one tries to bring the imaging or spectroscopic device to the bedside. For this task, one must foster strong collaborations with physicians who can help to identify physiological sites where optical techniques may be clinically practical and can offer new diagnostic knowledge and less morbidity over existing methods. An important intermediate step is the use of animal models for preclinical studies. Overall, this is a complicated path. However, the spectroscopic power of light, along with the revolution in molecular characterization of disease processes has created a huge potential for *in vivo* optical imaging and spectroscopy. Maybe the twenty-first century will be the second “*siècle des lumieres*.”

## 30.2 Infrared Thermal Monitoring of Disease Processes: Clinical Study

The relationship between a change in body temperature and health status has been of interest to physicians since Hippocrates stated “should one part of the body be hotter or colder than the rest, then disease is present in that part.” Thermography provides a visual display of the surface temperature of the skin. Skin temperature recorded by an infrared scanner is the resultant balance of thermal transport within the tissues and transport to the environment. In medical applications, thermal images of human skin

contain a large amount of clinical information that can help to detect numerous pathological conditions ranging from cancer to emotional disorders. For the clinical assessment of cancer, physicians need to determine the activity of the tumor and its location, extent, and its response to therapy. All of these factors make it possible for tumors to be examined using thermography. Advantages to using this method are that it is completely nonionizing, safe, and can be repeated as often as required without exposing the patient to risk. Unfortunately, the skin temperature distribution is misinterpreted in many cases, because a high skin temperature does not always indicate a tumor. Therefore, thermography requires extensive education about how to interpret the temperature distribution patterns as well as additional research to clarify various diseases based on skin temperature.

Before applying the thermal technique in the clinical setting, it is important to consider how to avoid possible error in the results. Before the examination, the body should attain thermal equilibrium with its environment. A patient should be unclothed for at least 20 min in a controlled environment at a temperature of approximately 22°C. Under such clinical conditions, thermograms will show only average temperature patterns over an interval of time. The evaluation of surface temperature by infrared techniques requires wavelength and emissive properties of the surface (emissivity) to be examined over the range of wavelengths to which the detector is sensitive. In addition, a thermal camera should be calibrated with a known temperature reference source to standardize clinical data.

Before discussing a specific clinical application of thermography, an accurate technique for measuring emissivity is presented in Section 30.2.1. In Section 30.2.2, a procedure for temperature calibration of an infrared detector is discussed. The clinical applications of thermography with Kaposi's sarcoma are detailed in Section 30.2.3.

### 30.2.1 Emissivity Corrected Temperature

Emissivity is described as a radiative property of the skin. It is a measure of how well a body can radiate energy compared to a black body. Knowledge of emissivity is important when measuring skin temperature with an infrared detector system at different ambient radiation temperatures. Currently, different spectral band infrared detector systems are used in clinical studies such as 3–5 and 8–14  $\mu\text{m}$ . It is well known that the emissivity of the skin varies according to the spectral range. The skin emits infrared radiation mainly between 2–20  $\mu\text{m}$  with maximum emission at a wavelength around 10  $\mu\text{m}$  [62]. Jones [63] showed with an InSb detector that only 2% of the radiation emitted from a thermal black body at 30°C was within the 3–5  $\mu\text{m}$  spectral range; the wider spectral response of HgCdTe detector (8–14  $\mu\text{m}$ ) corresponded to 40–50% of this black body radiation.

Many investigators have reported on the values for emissivity of skin *in vivo*, measured in different spectral bands with different techniques. Hardy [64] and Steketee [65] showed that the spectral emissivity of skin was independent of wavelength ( $\lambda$ ) when  $\lambda > 2 \mu\text{m}$ . These results contradicted those obtained by Elam et al. [66]. Watmough and Oliver [67] pointed out that emissivity lies within 0.98–1 and was not less than 0.95 for a wavelength range of 2–5  $\mu\text{m}$ . Patil and Williams [68] reported that the average emissivity of normal breast skin was  $0.99 \pm 0.045$ ,  $0.972 \pm 0.041$ , and  $0.975 \pm 0.043$  within the ranges 4–6, 6–18, and 4–18  $\mu\text{m}$  respectively. Steketee [65] indicated that the average emissivity value of skin was  $0.98 \pm 0.01$  within the range 3–14  $\mu\text{m}$ . It is important to know the precise value of emissivity because an emissivity difference of 0.945–0.98 may cause an error of skin temperature of 0.6°C [64].

There is considerable diversity in the reported values of skin emissivity even in the same spectral band. The inconsistencies among reported values could be due to unreliable and inadequate theories and techniques employed for measuring skin emissivity. Togawa [69] proposed a technique in which the emissivity was calculated by measuring the temperature upon a transient stepwise change in ambient radiation temperature [69,70] surrounding an object surface as shown in Figure 30.7.

The average emissivity for the 12 normal subjects measured by a radiometer and infrared camera are presented in Table 30.2. The emissivity values were found to be significantly different between the 3–5 and 8–14  $\mu\text{m}$  spectral bands ( $p < .001$ ). An example of a set of images obtained during measurement using an infrared camera (3–5  $\mu\text{m}$  band) on the forearm of a healthy male subject is shown in Figure 30.8.

FIGURE 30.7 Schematic diagram of the emissivity measurement system [70].

TABLE 30.2 Emissivity Values

Average normal forearm skin of 12 subjects	
Infrared camera (3–5 $\mu\text{m}$ )	$0.958 \pm 0.002$
Radiometer (8–14 $\mu\text{m}$ )	$0.973 \pm 0.0003$

FIGURE 30.8 (See color insert.) An example of images obtained from the forearm of a normal healthy male subject. (a) Original thermogram; (b) emissivity image; (c) thermogram corrected by emissivity.

An accurate value of emissivity is important, because an incorrect value of emissivity can lead to a temperature error in radiometric thermometry especially when the ambient radiation temperature varies widely. The extent to which skin emissivity depends on the spectral range of the infrared detectors is demonstrated in Table 30.2, which shows emissivity values measured at  $0.958 \pm 0.002$  and  $0.973 \pm 0.003$  by an infrared detector with spectral bands of 3–5 and 8–14  $\mu\text{m}$  respectively. These results can give skin temperatures that differ by  $0.2^\circ\text{C}$  at a room temperature of  $22^\circ\text{C}$ . Therefore, it is necessary to consider the wavelength dependence of emissivity, when high precision temperature measurements are required.

Emissivity not only depends on wavelength but is also influenced by surface quality, moisture on the skin surface, etc. In the infrared region of 3 to 50  $\mu\text{m}$ , the emissivity of most nonmetallic substances is higher for a rough surface than a smooth one [71]. The presence of water also increases the value of emissivity [72]. These influences may account for the variation in results.

### 30.2.2 Temperature Calibration

In infrared thermography, any radiator is suitable as a temperature reference if its emissivity is known and constant within a given range of wavelengths. Currently, many different commercial blackbody calibrators are available to be used as temperature reference sources. A practical and simple blackbody radiator with a

**FIGURE 30.9** Schematic diagram of temperature calibration system.

known temperature and measurement system is illustrated in Figure 30.9. The system consists of a hollow copper cylinder, a temperature controlled water bath and a precise temperature meter with probe. The height of the cylinder is 15 cm and the diameter is 7.5 cm. The cylinder is closed except for a hole in the center of the upper end which is 2 cm in diameter. To make the blackbody radiator, the inner surface of the cylinder is coated with black paint (3M Velvet Coating no. 2010) with emissivity of 0.93. Before the calibration,  $\frac{3}{4}$  of the cylinder is placed vertically in the water and the thermal camera is placed on the top of the cylinder in a vertical direction with a distance of focus length between the surface of the hole and the camera. The water temperature ranges from 18 to 45°C by increments of 2°C. This range was selected since human temperature generally varies from 22 to 42°C in clinical studies. After setting the water temperature, the thermal camera measures the surface temperature of the hole while the temperature meter with probe measures the water temperature. The temperature of the camera is calibrated according to the temperature reading of the temperature meter.

### 30.2.3 Clinical Study: Kaposi's Sarcoma

The oncology community is testing a number of novel targeted approaches such as antiangiogenic, anti-vascular, immuno- and gene therapies for use against a variety of cancers. To monitor such therapies, it is desirable to establish techniques to assess tumor vasculature and changes with therapy [73]. Currently, several imaging techniques such as dynamic contrast-enhanced magnetic resonance (MR) imaging [74–76], positron emission tomography (PET) [77–79], computed tomography (CT) [80–83], color Doppler ultrasound (US) [84,85], and fluorescence imaging [86,87] have been used in angiogenesis-related research. With regard to monitoring vasculature, it is desirable to develop and assess noninvasive and quantitative techniques that can not only monitor structural changes, but can also assess the functional characteristics or the metabolic status of the tumor. There are currently no standard noninvasive techniques to assess parameters of angiogenesis in lesions of interest and to monitor changes in these parameters with therapy. For antiangiogenic therapies, factors associated with blood flow are of particular interest.

Kaposi's sarcoma (KS) is a highly vascular tumor that occurs frequently among people infected with acquired immunodeficiency syndrome (AIDS). During the first decade of the AIDS epidemic, 15 to 20% of AIDS patients developed this type of tumor [88]. Patients with KS often display skin and oral lesions. In addition, KS frequently involves lymph nodes and visceral organs [89]. KS is an angio-proliferative disease characterized by angiogenesis, endothelial spindle-cell growth (KS cell growth), inflammatory-cell infiltration and edema [90]. A gamma herpesvirus called Kaposi's sarcoma associated herpesvirus (KSHV) or human herpesvirus type 8 (HHV-8) is an essential factor in the pathogenesis of KS [91]. Cutaneous

**FIGURE 30.10** (See color insert.) Typical multi-modality images obtained from a patient with KS lesion. The number “1” and “5” in the visual image were written on the skin to identify the lesions for tumor measurement. The solid line in the thermal and LDI demarks the border of the visible KS lesion. Shown is a representative patient from the study reported in Reference 95.

KS lesions are easily accessible for noninvasive techniques that involve imaging of tumor vasculature, and they may thus represent a tumor model in which to assess certain parameters of angiogenesis [92,93].

Recently, two such potential noninvasive imaging techniques, infrared thermal imaging (thermography) and laser Doppler imaging (LDI) have been used to monitor patients undergoing an experimental anti-KS therapy [94,95]. Thermography graphically depicts temperature gradients over a given body surface area at a given time. It is used to study biological thermoregulatory abnormalities that directly or indirectly influence skin temperature [96–100]. However, skin temperature is only an indirect measure of skin blood flow, and the superficial thermal signature of skin is also related to local metabolism. Thus, this approach is best used in conjunction with other techniques. LDI can more directly measure the net blood velocity of small blood vessels in tissue, which generally increases as blood supply increases during angiogenesis [101,102]. Thermal patterns were recorded using an infrared camera with a uniform sensitivity in the wavelength range of 8 to 12  $\mu\text{m}$  and LDI images were acquired by scanning the lesion area of the KS patients at two wavelengths, 690 and 780 nm.

An example of the images obtained from a typical KS lesion using different modalities is shown in Figure 30.10 [95]. As can be seen in the thermal image, the temperature of the lesion was approximately 2°C higher than that of the normal tissue adjacent to the lesion. Interestingly, in a number of lesions, the area of increased temperature extended beyond the lesion edges as assessed by visual inspection or palpation [95]. This may reflect relatively deep involvement of the tumor in areas underlying normal skin. However, the thermal signature of the skin not only reflects superficial vascularity, but also deep tissue metabolic activity. In the LDI image of the same lesion, there was increased blood flow in the area of the lesion as compared to the surrounding tissue, with a maximum increase of over 600 AU (arbitrary units). Unlike the thermal image, the increased blood velocity extended only slightly beyond the area of this visible lesion, possibly because the tumor process leading to the increased temperature was too deep to be detected by LDI. Both of these techniques were used successfully to visualize KS lesions [95], and although each measures an independent parameter (temperature or blood velocity), there was a strong correlation in a group of 16 patients studied by both techniques (Figure 30.11) [95]. However, there were some differences in individual lesions since LDI measured blood flow distribution in the superficial layer of the skin of the lesion, whereas the thermal signature provided a combined response of superficial vascularity and metabolic activities of deep tissue.

In patients treated with an anti-KS therapy, there was a substantial decrease in temperature and blood velocity during the initial 18-week treatment period as shown in Figure 30.12 [95]. The changes in these two parameters were generally greater than those assessed by either measurement of tumor size or palpation. In fact, there was no statistically significant decrease in tumor size overall. These results suggest that thermography and LDI may be relatively more sensitive in assessing the response of therapy in KS than conventional approaches. Assessing responses to KS therapy is now generally performed by visual measuring and palpating the numerous lesions and using rather complex response criteria. However, the current tools are rather cumbersome and often subject to observer variation, complicating the assessment

**FIGURE 30.11** Relationship between the difference in temperature and flux of the lesion and surrounding area of the lesion of each subject. A positive correlation was observed between these two methods ( $R = 0.8, p < .001$ ). (Taken from Hassan et al., TCRT, 3, 451–457, 2004. With permission.)

**FIGURE 30.12** (See color insert.) Typical example of lesion obtained from a subject with KS (a) before, and (b) after the treatment. Improvement after the treatment can be assessed by the thermal or LDI images after 18 weeks. Shown is a patient from the clinical trial reported in Reference 95.

of new therapies. The techniques described here, possibly combined with other techniques to assess vasculature and vessel function, have the potential of being more quantitative, sensitive, and reproducible than established techniques. Moreover, it is possible that they may show a response to therapy sooner than conventional than conventional means of tumor assessment.

### Acknowledgments

Special thanks go to Dr. Herbert Rinneberg (Physikalisch-Technische-Bundesanstalt, Berlin) and Dr. Brian Pogue (Dartmouth College) for providing the optical images. The authors also wish to express their thanks to Dr. Tatsuo Togawa, a former professor of the Institutes of Biomaterials and Bioengineering,

Tokyo Medical and Dental University, Tokyo, Japan for his valuable suggestions and allowing emissivity measurements to be performed in his lab. The authors also like to thanks Kathleen Wyvill and Karen Aleman for their help.
