ABSTRACT

A thermal design procedure for air cooled electronic circuit boards has been developed for the Hewlett-Packard Model 9845 desktop computer. The system of interactive programs, called THERMELEX, performs thermal analysis of printed circuit boards to predict either the junction temperatures for given power dissipation levels or the maximum power levels for given junction temperature limits. The system includes the following features: totally interactive with all input in question and answer format, simple data verification and correction capabilities, ability to store and retrieve circuit board descriptive data totally under program control, wide variety of output formats including tabular and graphical. By using internal selection of heat transfer correlations, the THERMELEX system depends only on input of physical parameters for thermal predictions.

TABLE OF CONTENTS

LIST OF FIGURES

NONMENCLATURE

Aair	Average area for cooling air flow	[m^2]
Agap	Area of bottom of component	[m^2]
Rl	Area for conduction in either a CPU or a circuit board lead	[m^2]
Apara	Area of the component experiencing parallel flow	[m^2]
Areg	Area of the region on the circuit board	[m^2]
Aspin	Surface area of the component lead	[m^2]
Astag	Area of the component experiencing stagnation flow	[m^2]
Axpin	Crossectional area of the component lead	[m^2]
Bdh	Height of circuit board (perpendicular to air flow)	[m^2]
Bdl	Length of circuit board (parallel to air flow)	[m^2]
Cpair	Heat capacity of the air	[J/Kg-degK]
CPU	Conduction Path Unit (size defined by user)	
Dgap	Distance between the component bottom and the circuit board	[m^2]
Dh	Hydraulic diameter	[m^2]
DIP	Dual Inline Package	
Epsb	Emissivity of the circuit board	
Epse	Emissivity of the component	
Fair	Volumetric air flow rate	[m^3/sec]

Fr	Roughness factor	
Gnu	Kinematic viscosity of air	[m^2/sec]
Gz	Graetz number	
Havg	Average height of the components present on the board	[m]
Hb	Heat transfer coefficient for the circuit board	[Watt/m^2-degK]
Hduct	Heat transfer coefficient for the duct formed by the circuit boards and equipment case	[Watt/m^2-degK]
He	Height of the component	[m]
Hpara	Heat transfer coefficient for areas receiving parallel air flow	[Watt/m^2-degK]
Hr	Dimension of region in the vertical direction or vertical distance between finite difference nodes	[m]
Hstag	Heat transfer coefficient for areas receiving stagnation air flow	[Watt/m^2-degK]
Kair	Thermal conductivity of cooling air	[Watt/m-degK]
Kb	Thermal conductivity of the circuit board	[Watt/m-degK]
Kl	Thermal conductivity of the board leads	[Watt/m-degK]
Kpin	Thermal conductivity of the component lead	[Watt/m-degK]
Le	Length of the component	[m]
Lpin	Length of component lead	[m]
Lr	Dimension of region in the horizontal direction or horizontal distance between nodes	[m]
Mair	Mass flow rate of cooling air	[Kg/sec]
Navg	Average number of component in a vertical column perpendicular to the air flow direction	

Npin	Number of leads on a component	
Nxr	Number of regions in the air flow of horizontal direction	
Nyr	Number of regions perpendicular to the air flow direction or vertical direction	
Perim	Wetted perimeter of the air duct	[m]
Pow	Energy dissipated in the component	[Watts]
Pr	Prandtl number	
Q	Rate of heat transfer	[Watts]
Qe-b	Total rate of heat transfer from the component to the circuit board	[Watts]
Q_1	Total rate of heat transfer out the bottom of a circuit board region	[Watts]
Q_2	Total rate of heat transfer out the right side of a circuit board region	[Watts]
Q_3	Total rate of heat transfer out the top of a circuit board region	[Watts]
Q_4	Total rate of heat transfer out the left side of a circuit board region	[Watts]
R	Thermal resistance for heat transfer	[deg K/Watt]
Re	Reynolds number	
Rb-conv	Total thermal resistance for convection from circuit board surface to the cooling air flow	[degK/Watt]
Rb-hor	Thermal resistance for conduction in the circuit board between nodes in the horizontal direction	[degK/Watt]
Rb-ver	Thermal resistance for conduction in the circuit board between nodes in the vertical direction	[degK/Watt]
Re-conv	Total thermal resistance for convection from component surface to the cooling air flow	[degK/Watt]

Rgap-cond	Conductive thermal resistance for the air gap between the component bottom and the circuit board	[degK/Watt]
Rgap-rad	Effective thermal resistance for radiation from the component bottom to the circuit board	[degK/Watt]
Rl	Total conductive resistance between finite difference nodes (centers of region)	[degK/Watt]
Rpara	Thermal resistance for heat transfer from area receiving parallel air flow	[degK/Watt]
Rstag	Thermal resistance for heat transfer from area receiving stagnation air flow	[degK/Watt]
Rtop-r	Effective thermal resistance for radiation from the top of the component to next board	[degK/Watt]
Rtote-b	Total thermal resistance between the component bottom and the circuit board	[degK/Watt]
Tair	Local air temperature	[degC, degK]
Te	Temperature of the component surface	[degC, degK]
Tb	Temperature of the board surface	[degC, degK]
Thb	Thickness of the circuit board	[m]
Tj	Temperature of the component junction	[degC, degK]
Vair	Velocity of the cooling air	[m/sec]
Wavg	Average width of the components present on the board	[m]
We	Width of the individual components	[m]
X	Direction parallel to cooling air flow also referred to as the horizontal direction due to orientation of circuit board picture on screen of computer	

Xi	Distance from the entrance of the cooling air	[m]
Y	Direction perpendicular to cooling air flow also referred to as the vertical direction due to orientation of circuit board picture on screen of computer	
Zb	Distance between circuit boards	[m , mm]

I. INTRODUCTION

A. BACKGROUND

Electronic components generally convert a significant fraction of the input power into internal joulian heating. When the components are large, widely separated, and air is permitted to circulate freely among them, this heat generated within the component is transferred to the environment through natural convection. Indeed, millions of pieces of home electronic equipment have operated reliably for years depending only on natural circulation for cooling. The major emphasis over the last 15 years has been a continuing effort toward a reduction in physical size of components and increased component density within electronic equipment. The military is particularly in need of smaller, more complex, yet reliable equipment that must often be sealed from an extremely hostile environment. This results in the need for more efficient cooling methods.

The age of large scale integration (LSI) is here. Although the power dissipated in each active junction within a component has greatly decreased, the large number of heat sources on each chip has created serious heat removal problems. There is a genuine need for electronic designers to not only be aware of the problems associated with higher

temperatures, but they must also be prepared to solve those problems. References [1] through [10] are a sampling of the many sources that indicate the increased emphasis on cooling problems throughout the electronics community.

The need to operate electronic equipment with maximum junction temperatures below those levels that result in failure is well recognized, but even moderately high temperatures in electronic components result in progressive deterioration and reduced reliability. A generally accepted thumb rule is: for every 10 deg C increase in junction temperature, the lifetime of a component will decrease by one-half. [3, 7] The increasing costs associated with each failure make it imperative to address reliability during the equipment design phase and to provide sufficient cooling to maintain temperatures as low as practical.

There are many methods of removing the heat dissipated within electronic components. These methods include the natural air convection previously mentioned, thermo-electric devices, heat pipes, cold plates and even complex refrigeration systems which use pumped liquid coolants [8]. The complex systems required for these solutions can lead to lower reliability through increased probability of failures in the cooling system. While many of these methods can allow extremely high power densities for specific applications, the most widely used method for cooling of components

mounted on printed circuit boards is forced air cooling. Air is readily available, abundant, non-corrosive, non-toxic, non-flammable, dielectric, and is easily pumped using readily available fans and blowers. For those situations where there is a need to seal the equipment, interior cooling air is often circulated through heat exchangers.

All too often the problem of cooling the electronic components is attacked after the circuit boards have been designed or even produced and assembled [9]. In some cases, the need for increased cooling is recognized only after repeated failures in service have resulted in unhappy users and excessive repair costs. At best both the electronic design and the thermal design progress concurrently but are worked on by separate design groups. These groups may have conflicting range goals that can interfere with the important long range goal of reliability.

Many of the efforts to directly involve the electrical designer in the thermal problems are directed towards overall system cooling. Reference [11] details a thermal design program called VENTBOX. VENTBOX treats a cabinet enclosure with entire circuit boards modeled as distributed heat sources. This program fails to address the problems of individual components and, therefore, is unable to analyze the circuit board.

Electronic circuit analysis programs are often utilized in the thermal analysis of circuit boards [12 and 13]. This

technique requires the development of an equivalent thermal circuit, usually by a packaging engineer, and thus the thermal design is removed from the hands of the electronic designer. Reference [14] details a thermal analysis program for circuit boards that is much more accessible to an electronic designer since the inputs are physical dimensions and types of components rather than equivalent thermal network parameters.

All these programs share a major weakness in that they depend on a large general purpose computer facility. This not only can result in excessively long turn-around times in batch processing, but also the expense of computer time may become a factor. In addition, the input data typically consists of long lists of numbers that must be in the proper format with the correct option selection codes. Likewise the output also consists of even longer lists of numbers with the key information hidden in their midst.

One solution to automated thermal design and analysis of avionics systems is being developed as a joint project by the Air Force Flight Dynamics Laboratory at Wright Patterson Air Force Base and Boeing Aerospace Company. The ITAD (Integrated Thermal Avionics Design) system is expected to include many existing analysis programs and a large ever growing data base containing reliability parameters. It is anticipated that ITAD will be accessed by user through both batch methods and interactively through color graphics

terminals. The scope of this project is enormous and the benefits to the system designer will be many, provided he has access to the large computer at Wright Patterson Air Force Base [15, 16].

Another solution on a much smaller scale is to create a program for a compact, stand alone desktop computer that is easily accessible to the designer of electronic circuit boards. Such a system, if interactive and "friendly" to the casual user, would allow rapid evaluation of various circuit board designs at the conceptual level. Rejection of those designs with poor thermal characteristics could then occur before they leave the drafting table saving both future efforts and dollars.

B. OBJECTIVES

The main objective of this thesis was to develop an interactive thermal analysis program utilizing the Hewlett-Packard 9845 desktop computer. It was considered important to include the following features:

1. Simplicity of operation: All data input and control of program flow are done in a question and answer format including specific instructions with each question.

2. Graphical data checking: Display circuit board replicas on the screen both for verification of input and to provide a more useful form of output.

3. Data correction capabilities: Use interactive methods to allow correction of portions of the data without the need to repeat all the input.

4. Automatic storage and retrival of data: Circuit board descriptions should be written to and read from mass storage devices using simple questions and answers rather than requiring specific knowledge of operations of the devices.

5. Analysis methods hidden: Various empirical heat transfer correlations should be used based on the physical descriptions and the user should be relieved of the need to make decisions concerning the details of the heat transfer analysis methods.

6. Sensitivity analysis: Allow automatic parameter changes to investigate the effects on the thermal performance of these changes with plotted data.

II. DESCRIPTION OF THE THERMELEX SYSTEM

A. GENERAL

1. The Computer

The name THERMELEX will be used to refer to the system of interactive programs created to perform thermal analysis of air cooled electronic circuit boards. The programs are written for the Hewlett-Packard Model 9845 desktop computer using the Hewlett-Packard extended version of the basic language. A sophisticated operating system hides the complexity of the 9845 from the user and provides protection from his mistakes yet provides the power and flexibility needed for application programs such as the THERMELEX system.

The computer used to create and debug THERMELEX is the 9845A with 64 k bytes of read/write memory (option 203), internal printer (option 500) and graphics package. In addition, dual tape drives and dual floppy disks were utilized in the development of the system. These additional mass storage devices provided considerable increase in the convenience and speed of storage and retrieval operations but THERMELEX is designed to operate with only the standard tape drive. Recent advances in the internal electronics have resulted in this model being superseded by the 9845B model with larger memory capabilities and several other features.

THERMELEX is available in either an A-version or B-version for use in the respective model of the 9845.

Figure 1 shows the 9845A but the 9845B is identical in physical appearance except for the name tag. The screen at the top will display the messages from the system to the user, what is typed by the user and the output from the THERMELEX programs. This output may be printed on the screen in what is known as the alpha mode or it may be presented as pictures and words from the graphics mode. Output of either mode may also be produced on the thermal printer above the keyboard in the inclined area. Directly underneath the screen there are four pull-out reference cards that explain error messages and other operating conditions that may occur. At the extreme upper right corner of the sloping section is the standard tape transport (:T15) for mass storage of programs and data.

The keyboard contains not only a set of standard typewriter keys but also several other groups of keys that are important to THERMELEX. The numeric keys at the lower right allow easy entry of numbers as an alternative to those in the alphanumeric group of keys and allows numeric calculations to be performed even during execution. Between these groups are the gold colored program control keys. All responses to questions are followed by pressing the CONT key at the bottom of this column of keys. The group of special

function keys in the upper right are defineable by the user or from program control. They are also used in THERMELEX as priority interrupts to simplify the input of data. This use of these keys is further explained later. The final key of interest to the THERMELEX system user is the AUTOST key in the lower right corner of the EDIT/SYSTEM FUNCTIONS group. This key allows automatic loading and execution of the first program in the THERMELEX system. Explanation for its use is found in Appendix 1, the User Instructions. For further explanations of the features of the Hewlett-Packard model 9845 computer, see Ref [17] supplied with the computer.

2. THERMELEX System

Due to the memory limitations of the 9845A, THERMELEX is divided into three major programs which are generally brought into case from mass storage under program control as they are needed. However, each program is designed to stand alone which can allow the experienced user to bypass some of the questions and answers required to help the inexperienced users. AUTOST is the first program of the three; here several pages of user instructions (see Appendix 1) may be printed, the special function keys are defined and the user is directed along a path to follow towards the other programs. In BOARDS, the circuit board descriptive data is entered, verified and stored on any one of the mass storage devices. The user may also elect to produce a printed copy of the input data for

his records. The THERML program performs the thermal analysis and provides output in various tabular or graphical forms. These three major programs will be described in more detail in the pages that follow.

There are also several smaller files in the system. BDSKEY and STDKEY alter the definitions of the special function keys. TNAMES contains a listing of all variable names and program section names with explanations to aid in any future modifications of the THERMELEX system. DEMO-P and DEMO-T are data files containing example circuit board descriptive data to allow demonstrations of the system and to help the new user become familiar with the capabilities.

B. AUTOST

1. General

AUTOST is the driver program for the system. This name allows the program to be automatically loaded and executed if the AUTOST key is latched down and if the tape containing the THERMELEX system is in the standard right-hand tape drive (:T15) when the main power switch is turned on. Regardless of how the program is loaded, the first question will be concerning the location of THERMELEX. The program will ask which mass storage device contains the system since this is necessary for correct program control. At this point, the program defines the default mass storage device using the "MASS STORAGE IS "---" command, and the

default mass storage device should not be altered while using THERMELEX.

2. Instructions

AUTOST will provide a printed set of user instructions either on the screen in short segments or on the thermal printer in 8.5 by 11 inch pages. These instructions present an overall system view and are intended to familiarize the inexperienced user and supplement the extensive instructions and prompts that are presented on the screen in all sections of THERMELEX.

3. Special Function Keys

AUTOST redefines the special function keys as required for the system and can provide a paper key-code overlay as a substitute for the plastic model (Hp Part #7120-6164). Figure 3 shows both styles. The paper style may be used as a guide for filling in the appropriate blanks on the plastic version.

4. Option List

Finally, AUTOST provides a list of options for the user to select from. He may load either of the other two programs in THERMELEX or produce a complete copy of the programs in the system through selection of the appropriate number from the menu of options. This technique is employed throughout the system whenever possible because of the simplicity involved in entering a single number over other methods of option selection.

5. The Copy Option

The copy option is included as a built-in feature since there are many separate files in THERMELEX and a separate command is required for each file to be copied. Any mass storage device may serve as the destination for the system; however, when copying to tape, it is suggested that it be blank due to the number of open blocks required. Following completion of this option, program control returns to option list. It is expected that the first option (keyboard entry of circuit board description) is the most likely to be used and the description that follows assumes this path.

C. BOARDS

1. General

The major purpose of the BOARDS program in the THERMELEX system is to provide a simple method for input of the descriptive data needed in THERML for the creation of the thermal model and the analysis. This data includes the geometric and material properties of the circuit board as well as what components are on the circuit board. These components are limited to DIP's (Dual Inline Packages) and chip carriers (FLAT Packs). The thermal model used for the analysis of the board is a finite difference scheme and the physical location of the components is approximated by the locations of the finite regions created by the user.

The descriptive data may be entered from the keyboard in response to simple questions; or, it may be retrieved from mass storage data files previously recorded using BOARDS. The instructions included as Appendix 1 provide specific explanations of how to use this program.

2. Checking of Input Data

All input data is displayed using either the graphics capabilities of the 9845 or with printed lists produced on the screen or paper. The user may, therefore, easily verify the validity of the data he has entered. This feature is included whenever possible throughout THERMELEX.

3. Correction of Input Data

There are many opportunities to change the descriptive data using the same question and answer format of interactive programming. At no time is it necessary for the user to have extensive knowledge of the program's internal workings or the machine level commands performed within the program. As a further means of correcting past errors, the backup feature built into the THERMELEX system makes it extremely easy to return to previous questions. This feature is accessed by depressing the special function key (Ko) in place of a response to a request for input. Program control will jump back to the previous question to allow re-entry of data. Repeated use of Ko allows backing up to any desired point and resumption of program flow from that point.

4. The Circuit Board

To describe the geometry of the circuit board under investigation, the user must enter the length, width, thickness and the thermal conductivity of the circuit board. With no input, the thermal conductivity will be assigned a default value of 0.29 Watts/m-degC, a representative value for the bonded glass laminates generally used for construction of circuit boards. The length parameter is defined to be in the direction of air flow regardless of which dimension is the largest.

In order to create the finite difference thermal model, the board must be divided into logical regions by placing any number of equally spaced vertical lines and any number of equally spaced horizontal lines on the board up to a total of 50 regions. More regions would be possible in the 9845B due to the larger memory capacity but this would require some program changes. Each region will either contain a component assumed to be centered in the region or will be empty. Since there may be regions with no components, there is no unique set of descriptive data for a given circuit board design. The user is encouraged to try different combinations of horizontal or x regions and vertical or y regions to describe a circuit board. Figure 4 shows two such possibilities for a board with six 14 pin DIP's. Both the six region model and the 42 region model describe the same board. Experience is helpful in making decisions as

to how to divide the board and some boards may not fit into the constraints imposed by THERMELEX, but many will.

5. The Components

Each of the defined regions will be empty or contain one of the following components: 14, 16, 24, 40 pin DIP's with either vertical or horizontal orientation and 16, 24, 40, 64 pin chip carriers. These components will be assured to be centered in the region (with the exception of the 40 pin DIP which will be assumed to occupy two regions). The input of component type for each region is via the special function keys. A special paper key-code overlay for use in this component input section may be provided if a plastic version is not available, see Figure 5. As a flashing cross appears in each of the regions, the appropriate special function key is depressed. This defines the type of component, length, width, orientation and draws the component on the screen for visual verification of corrections. After all regions have been defined, corrections are possible through removal and replacement of components using the same special function keys.

6. Thermal Conduction Paths

Each of the defined regions on the board may exchange energy with the adjacent regions via conduction through the board itself and any thermally conductive material added to the board such as electrical leads. In addition, many circuit

board designs involve metal conduction rails that provide both mechanical support and a method to transport the heat from the componets. There are provisions in BOARDS to model either the electrical leads or the conduction rails. For circuit boards without conduction rails, the user specifies the average lead width (mm), thickness and thermal conductivity of the lead material. These geometric parameters are used to determine the thermal resistance of a single lead connecting the region centers or nodes.

When conduction rails are included on the circuit board, the effects of the electrical leads are ignored. To allow modeling of rails that may have different widths, the concept of a conduction path unit (CPU) is introduced. A CPU is defined to be .1 mm in width but the user specifies the thickness and conductivity of the material. These parameters are used to determine the thermal resistance of a single CPU connecting the region centers.

With the thermal resistance of single CPU or electrical lead determined, the user need only specify the number of such resistances that connect the circuit board regions. For example, if a conduction rail is 5.8 mm in width, it may be modeled as containing 58 CPUs. While the concept of CPUs is totally artificial, this concept does allow modeling of the Navy Standard Electronic Module (SEM) and Improved Standard Electronic Module (ISEM) for those situations when these modules are used in forced air cooled systems.

With the physical description of the circuit board now complete, the user may elect to produce a picture of the circuit board from a dump of the graphics to the internal printer. Pressing special function Key 3 will produce a picture such as Figure 6. This picture may be used as a final verification of the validity of the circuit board description that has been entered. The remaining descriptive data to be entered concerns the component parameters.

7. Temperature or Power Input

The user must specify either the average power to be dissipated in each component or the maximum junction temperature. When power levels are specified, the steady state junction temperatures will be calculated in THERML. When junction temperatures are specified, the maximum allowable component power levels will be calculated. In either case, the user must also specify a case to junction thermal resistance for each component. This is usually supplied by the manufacturer and provides the means in the thermal model to link the component power level and junction temperature to the case surface temperature. Figure 7 shows the data summary sheet provided after the data has been entered and verified.

8. Storage of Data

Although it is possible to load THERML and perform the thermal analysis directly since all data is passed

through a common block, it is strongly urged that the circuit board description be stored on mass storage. A few simple answers allows the storage to tape or disk for retrieval at a later time. This data file may be accessed, verified, altered and recorded back to mass storage using BOARDS to investigate the effects that changes in design have on the temperatures or power levels obtained in THERML. Both Appendix 1 and the program provide easy to follow instructions for retrieval of previously recorded descriptive data files.

Totally under program control, the third major program in the THERMELEX system, THERML will be loaded at the direction of the user and execution started at the proper entry point.

D. THERML

1. General

Recall from the previous discussion that BOARDS establishes all the parameters that describe the circuit board. While the major purpose of THERML is to analyze the thermal performance, it must first establish the parameters that describe how the circuit board is installed and cooled, such as the spacing between boards, volumetric air flow per board and inlet temperature of the cooling air. Using the total set of board and installation parameters, the thermal model is set up, solved and the results presented.

The approach taken in the thermal analysis is to construct an approximate thermal network [7] for every path

of heat transfer from the components and the circuit board. The thermal resistance (R) for each path is calculated from the set of parameters and if a temperature difference (ΔT) for that path is known, the expression:

$$Q = \frac{\Delta T}{R}$$

will determine the rate of heat transfer (Q) for that path. When the rate of heat for a given path is known, the expression:

$$\Delta T = (Q) \times (R)$$

will determine the temperature difference.

An overall heat balance for the components and the circuit board, with all the heat that is generated going into the cooling air stream, is used to determine either the steady state junction temperatures (when component power levels are specified) or the component power levels (when the junction temperatures are specified).

2. Air Flow - Thermal Model

The cooling air flow is assumed to come from an infinite heat sink which supplies air at a constant inlet temperature. All the heat dissipated within the components is assumed to enter the air stream with no heat conducted into the card guides or electrical connectors. These guides and the mechanical support sections of the connectors are typically made of plastic with high resistance to heat transfer and this assumption leads to conservative estimates.

As the air travels from inlet to outlet, it is assumed to remove heat from both the component surfaces and the surface of the circuit board. It is further assumed to travel in air lanes defined by the height of each region perpendicular to air flow and not mix until the outlet. As the air removes heat from each region, the local air temperature (Tair) will increase. The process is described by the general equation:

$$\text{Tair at } X + \Delta X = \text{Tair at } X + \frac{Q \text{ added in } \Delta X}{(\text{Mair}) \times (\text{Cpair})}$$

where Mair = Mass flow rate of air [kg/sec]

Cpair = Heat capacity of air [J/kg-degk]

ΔX = length of a region in the air flow direction

This process results in the temperature of the cooling air stream being modeled as a series of steps as the air travels from inlet to outlet within an air flow lane. The local air temperature and the convective resistance determine the local convective heat transfer.

The air velocity is determined from the physical description entered by the user and this air velocity is used to determine the convective resistances. Recall that circuit board spacing (Zb), board height (Hb) and volumetric air flow rate (Fair) are part of the descriptive data set previously entered. With no components present, the air velocity (Vair) would be defined by:

$$\text{Vair} = \frac{\text{Fair}}{(\text{Zb}) \times (\text{Hb})}$$

However, the components tend to reduce the air flow area (Aair) by blockage. The average blockage area is determined by calculating the average number of components in a vertical column of regions perpendicular to the air flow. In addition, the average width (Wavg) and height (Havg) of the components is determined and the average air flow area calculated using:

$$Aair = (Zb) \times (Hb) - (Navg) \times (Havg) \times (Wavg)$$

This area is used to determine the air velocity from:

$$Vair = \frac{Fair}{Aair}$$

In addition the average area is used to determine the wetted perimenter (Perim) of the air duct formed by the boards according to:

$$Perim = 2Hb + 2Zb + 2\ (Navg) \times (Havg)$$

The hydraulic diameter (Dh) is therefore:

$$Dh = \frac{4\ Aair}{Perim}$$

which is also used in calculations of some of the heat transfer coefficients.

3. <u>Components - Thermal Model</u>

All heat generated within the components must be transferred away through conduction to the board, radiation to the board and to some radiation sink, and through convection to the cooling air. Figure 8 shows each of the thermal networks for heat transfer.

DIP components are usually mounted by soldering the electrical leads to the circuit board electrical conductors (Figure 9). These connector pins also act as low resistance thermal conductors between the component and the circuit board. The total thermal resistance from the component to the circuit board may be calculated from the cross sectional area of each pin (Axpin), the length of the pin (Lpin), the thermal conductivity of the pin material (Kpin) and the number of pins (Npin) using the expression:

$$Rpin = \frac{Lpin}{(Kpin) \times (Apin) \times (Npin)}$$

There is also a small gap between the bottom of the component case and the circuit board. Figure 9 shows the mounting for DIP cases where this gap is on the order of one mm; for chip carriers, this distance is smaller yet. Due to the small distance (Dgap) involved, it is assumed that no convection occurs in this gap and that the conductive resistance of the air gap (Rgap-cond) may be calculated from the expression:

$$Rgap\text{-}cond = \frac{Dgap}{(Kair) \times (Agap)}$$

where Agap represents the surface area of the bottom of the component and Kair represents the thermal conductivity of the air.

The component case will also radiate energy to the circuit board. Assuming the gap to act as two parallel

plates of equal areas with emissivities of Epsb and Epse, the heat transfer rate may be calculated (Ref [18]) from:

$$Q = \frac{(Sig) \times (Agap) \times (Te^4 - Tb^4)}{\frac{1}{Epsb} + \frac{1}{Epse} - 1}$$

where:

Sig = Stefan-Boltzman constant

$(5.67 \times 10^{-8} \frac{Watts}{m^2 - degK^4}$

Te = Component surface Temperature (degK)

Tb = Circuit board Temperature (degK)

This radiation term may be simplified by expanding $(Te^4 - Tb^4)$ in a Taylor series about Te and retaining only the linear portion of the series. When this is done, an effective gap radiation resistance (Rgap-rad) may be calculated from:

$$Rgap\text{-}rad = \frac{Epse + Epsb - (Epse)(Epsb)}{(r) \times (Sig) \times (Epse) \times (Epsb) \times (Te^3)}$$

Since the component case temperature (Te) is an unknown, this resistance will be recalculated as the solution progresses.

These three resistances (Rpin, Rgap-cond, Rgap-rad) may be combined into a total resistance between the component and the circuit board (Rtote-b). When the component is a chip carrier, the air gap and lead length are assumed to be one-tenth that of the DIP case [13].

Although the radiation heat loss from the component is extremely small and normally neglected in thermal analysis of electronic circuit boards, it is included here for completeness.

The component will radiate to the other components and the back of the adjacent circuit board. For the purposes of the thermal model under discussion, it is assumed that radiation is from the top of the component to the adjacent board and that this adjacent board temperature is the same as the board temperature below the component. It is further assumed that the area of the circuit board is much greater than that of the component. Using the same linearization technique previously discussed results in the expression:

$$Rtop\text{-}r = \frac{1 - Epse}{(4) \times (Sig) \times (Epse) \times (Ae) \times (Te^3)}$$

for the effective thermal resistance for radiation from the top of the component to the adjacent circuit board.

Convection heat transfer to the air, the final heat loss path from the component, depends on the heat transfer coefficient and the area for that mode of heat transfer. The component is assumed to experience two separate modes of convection. Those portions of the component that are perpendicular to the air stream are assumed to experience a stagnation form of air flow while the top and sides see parallel air flow. Recall that air flow is defined as being from left to right as required for data entry in the BOARDS program. When component types are entered as being horizontal or vertical using the special function keys, the component length (Le) and width (We) parameters are set such that Le is along the air flow direction and We is perpendicular to

the air flow. The standard correlation for plane stagnation flow may be written as: Ref [19]

$$Hstag = (.57) \times (Kair) \times (Pr^{.4}) \times \left(\frac{Vair}{(We) \times (Gnu)}\right)^{\frac{1}{2}}$$

where Hstag = Heat transfer coefficient for areas receiving stagnation air flow

Pr = Prandtl number for air

Gnu = Kinematic viscosity for air

Using the component height (He), the area for stagnation heat flow (Astag) may be calculated from:

$$Astag = (2) \times (We) \times (He)$$

The portions of the component that are parallel to the air flow (top and sides) are assumed to experience the same heat transfer coefficient that would occur in a smooth duct modified by a roughness factor (Fr) to account for the presence of the components acting to increase this heat transfer coefficient (Hpara). Hpara depends on the Reynolds number (Re) determined by:

$$Re = \frac{(Vair) \times (Dh)}{Gnu}$$

In the entrance region of the duct formed by the circuit boards, up to a distance of approximately ten hydraulic diameters, the flow is assumed to be laminar. Reference [20] contains the following correlation for the heat transfer

coefficient in the entrance region of a smooth duct:

$$Hduct = \frac{(.664) \times (Kair)}{(1.1) \times (Dh)} \left[\frac{(Gz) \times (1+(7.3) \times (\frac{Pr}{Gz})^{\frac{1}{2}}}{Pr} \right]^{\frac{1}{2}}$$

where Gz is the Graetz number defined as:

$$Gz = \frac{(Re) \times (Pr) \times (Dh)}{Xi}$$

and Xi is the distance from the entrance of the cooling air flow.

The value of the heat transfer coefficient predicted from the above equation has been found to be low from comparisons to experimental data of Ref [12] and Ref [14]. The expression:

$$Fr = 1 + \frac{5 \times (Perim - (2) \times (Bdh) - (2) \times (Zb))}{Perim}$$

has been created to adjust the predicted heat transfer coefficient for the rough duct. The expression reduces to one when no components are present and is less than two for all reasonable board constructions. The resulting heat transfer coefficient that is used for the parallel sides (Hpara) is therefore:

$$Hpara = (Hduct) \times (Fr)$$

For positions beyond the entrance length the flow may be laminar or turbulent and the appropriate heat transfer correlation must be chosen. The transition from laminar to turbulent is assumed to occur at a Reynolds number of 1000

since the components act as turbulence promoters for the air flow. For laminar flow, the expression:

$$\text{Hduct} = \frac{(5.4) \times (\text{Kair})}{\text{Dh}}$$

is used and the result modified with the roughness factor (Fr) to obtain Hpara. For turbulent flow the Dittus-Boelter relationship is used:

$$\text{Hpara} = \frac{(.023) \times (\text{Re}^{.8}) \times (\text{Pr}^{.4}) \times (\text{Kair})}{\text{Dh}}$$

Heat is convected not only off the top and sides of the components but also from the surface of the leads or pins. Since the thermal conductivity of the pin material is so high, their surface is assumed to have the same temperatures as the surface of the component. The effective component parallel side area for heat transfer is, therefore, determined from:

$$\text{Apara} = (\text{Le}) \times (\text{We}) + 2(\text{Le}) \times (\text{He}) + (\text{Aspin}) \times (\text{Npin})$$

where Aspin is the surface area of the pins that experience parallel air flow. The thermal resistances for convection from the component may then be calculated from:

$$\text{Rpara} = \frac{1}{(\text{Hpara}) \times (\text{Apara})} \qquad \text{and,}$$

$$\text{Rstag} = \frac{1}{(\text{Hstag}) \times (\text{Astag})}$$

These two resistances may then be combined as parallel resistances to give a total convective thermal resistance from the component to the air (Re-conv) of

$$\text{Re-conv} = \frac{(\text{Rpara}) \times (\text{Rstag})}{(\text{Rpara}) + (\text{Rstag})}$$

Returning now to the basic premise that all the heat produced within the component must be transferred through one of the heat paths illustrated in Figure 8, the heat balance equation for the Ith component is:

$$\text{Pow (I)} = \text{Qto board} + \text{Qto air} + \text{Qrad off top}$$

utilizing the general expression for heat flow as a function of temperature difference. This may be expressed as:

$$\text{Pow (I)} = \frac{\text{Te(I)} - \text{Tb(I)}}{\text{RToTe-b(I)}} + \frac{\text{Te(I)} - \text{Tair(I)}}{\text{Re-conv(I)}} + \frac{\text{Te(I)} - \text{Tb(I)}}{\text{Rtop} - \text{R(I)}}$$

This expression may be rearranged and solved for the component temperature (Te). The resulting expression is used to eliminate Te from the final set of equations that are solved for the set of board temperatures.

4. The Circuit Board - Thermal Model

The circuit board has been divided into regions as determined by the user while entering the circuit board description in program BOARDS. Each of the regions will lose or gain heat by the normal processes of conduction,

convection and radiation. In this thermal model, radiation from the circuit board regions is neglected due to the lower temperatures of the circuit boards. The board temperature (Tb) is assumed to be uniform within a given region for purposes of convective heat transfer to the cooling air stream. For purposes of calculating the heat conducted between regions, the temperature differences are assumed to exist over the distance between the centers of the regions. These region centers are the nodes in the finite difference model used to analyze the circuit board.

The surface of the board forms part of the air duct previously mentioned in the discussion concerning the calculation of the convective heat transfer coefficient from the parallel sides of the components (Hpara). The heat transfer coefficient of the board varies with distance from the air centered in the regions, the convective heat transfer coefficient for the board (Hb) is assumed to be equal to Hpara. The area for heat transfer from each region (Areg) includes both sides but excludes any area under the component (Ae) since the air is assumed not to flow in the small gap between the component and the circuit board. The area (Areg) is calculated from the equation:

$$\text{Areg} = \frac{(2) \times (\text{Bdl}) \times (\text{Bdh})}{\text{Nreg}} - \text{Ae}$$

where Bdl = Length of circuit board

Bdh = Height of circuit board

The convective resistance from the circuit board region (Rb-conv) is therefore:

$$\text{Rb-conv} = \frac{1}{(\text{Hb}) \times (\text{Areg})}$$

The conduction of heat within the circuit board material and any added conductive material is assumed to occur between the nodes located at the centers of each region. For a given region, this heat flow is assumed to occur only out the four sides of the region. The distance between nodes in the horizontal or air flow direction (Lr) is calculated from the circuit board length (Bdl) and the number of regions in the horizontal direction (Nxr). The expression used is:

$$\text{Lr} = \frac{\text{Bdl}}{\text{Nxr}}$$

Likewise, the vertical spacing between nodes (Hr) is calculated as:

$$\text{Hr} = \frac{\text{Bdh}}{\text{Nyr}}$$

These distances are used with the circuit board thickness (Thb) and the circuit board material thermal conductivity (kb) to determine the base board conductive resistances in both the vertical (Rb-ver) and horizontal direction (Rb-hor). The expressions used are:

$$\text{Rb-ver} = \frac{\text{Hr}}{(\text{kb}) \times (\text{Lr}) \times (\text{Thb})}$$

and

$$Rb\text{-}hor = \frac{Lr}{(kb) \times (Hr) \times (Thb)}$$

The conductive resistances in the material added to the circuit board is treated in the same manner since these materials are also assumed to connect the nodes. The conductivity of the material (kl) and physical area (al) have been specified for either a conduction path unit (CPU) or electrical lead. These are used in the expressions:

$$Rl\text{-}ver = \frac{Hr}{(kl) \times (Al)}$$

and

$$Rl\text{-}hor = \frac{Lr}{(kl) \times (Al)}$$

to determine the thermal resistance for conduction in a single conduction path. This resistance is divided by the number of such paths to determine the total conductive resistance of the material added to the circuit board.

This resistance is assumed to be in parallel with the conductive thermal resistance of the bare circuit board and a net conductive thermal resistance is calculated for each of the four directions using a normal product-over-sum formula for parallel resistances. Figure 10 shows how a typical region would thus be connected to the four adjacent regions. The values of these conductive thermal resistances are stored in a two dimensional array, Rl (I,J), where the

first index represents the region number and the second index is the direction number (1, 2, 3, 4). These numbers represent bottom, right side, top, and left side, respectively. For example, Figure 10 shows how Rl (I,2) connects region number I and region number I + 1. For those regions on the edges of the circuit board, the conductive thermal resistance in the direction off the board are set to very high value due to the assumed adiabatic boundary conditions for all edges. The set of conductive thermal resistances, Rl (I,J), is used in the heat balance for the circuit board.

With the component treated as the source of heat for the circuit board, one may again apply a simple heat balance for a region as follows:

$$Qe\text{-}b = Qconv + Q_1 + Q_2 + Q_3 + Q_4$$

where Qconv represents the heat transfer to the cooling air and Q_1 through Q_4 represent the heat conducted to the adjacent regions as shown in Figure 10. This expression may be written for Region I as:

$$\frac{Te(I) - Tb(I)}{Rtota\text{-}b} = \frac{Tb(I) - Tair(I)}{Rb\text{-}conv} + \frac{Tb(I) - Tb(I + Nxr)}{Rl(I,i)}$$
$$+ \frac{Tb(I) - Tb(I + 1)}{(Rl(I,2)} + \frac{Tb(I) - Tb(I\text{-}Nxr)}{Rl(I,3)}$$
$$+ \frac{Tb(I) - Tb(I\text{-}j)}{Rl(I,4)}$$

As previously stated, the heat balance equation for the component derived in Section 3 may be solved for Te(I) and that expression

used to eliminate Te(I) from the equation above. The only unknowns will then be the board temperatures. A heat balance for every region may be performed resulting in Nreg simultaneous algebraic equations. The coefficients of these equations may then be collected into a matrix and solved using an LU decomposition method [21].

5. <u>The Analysis</u>

In performing the thermal analysis of the circuit board, there are two separate situations to be considered: 1. Specified component power - determine steady state junction temperature; 2. Specified junction temperature - determine the maximum power allowable. For the first situation a case temperature (Te) is assumed for each component since this is necessary to determine the effective radiation resistances. All thermal resistances and the local air temperatures are then calculated using the given variables. The resulting system of Nreg simultaneous equations is solved using LU decomposition for the temperature of each region of the circuit board Tb.

This set of board region temperatures is used to determine the set of component case temperatures using the expression for Te determined from the heat balance of the component. These component temperatures are compared to those from the previous iteration. If the largest difference between any of the temperatures is less than the convergence criterion established by the user (default .1 degC), the

results are presented in the graphics mode on a fascimile of the circuit board as shown in Figure 11.

In the display of the circuit board, each region contains the component type, junction temperature, power level and case temperature for the component in that region. Empty regions contain only the temperature of the circuit board. Those junction temperatures that are within 5% of the maximum are starred (**) for easy reference. This output is dumped to the internal thermal printer to provide a hard copy.

If convergence has not been reached, the new case temperature is used to calculate new radiation thermal resistances and the new system of equations solved. Figure 12 shows the intermediate display of all temperatures that is presented on the screen while the next iteration is in progress. If longer than 20 lines, the maximum display area for output on the screen, this display may be moved up or down with the display control keys at the center top of the keyboard (see Figure 2). Convergence typically occurs in less than four iterations when solving for component junction temperatures.

For the second situation with specified junction temperatures (Tj), a power level of .25 watts is assumed for each component. The component case temperature may then be determined from the expression:

$$Te = Tj - \frac{Pow}{Rj\text{-}c}$$

where Rj-c represents the case to junction thermal resistance set by the user. As in the first situation, all the thermal resistances and the local air temperatures (Tair) are calculated. It is important to note that Tair depends on the assumed power levels since these values will change with each iteration. The resulting system of simultaneous equations is again solved for the board region temperatures and the component case temperatures. The resulting component power levels for each region are determined from the expression

$$\text{Pow} = \frac{\text{Te} - \text{Tb}}{\text{Rtote-b}}$$

This component power level for each component is compared to the results of the previous iteration or the assumed values for the first iteration. Convergence is assumed when the largest percentage difference from these comparisons is less than the convergence criterion established by the user (Default 1%).

The output is presented in the same manner as before except those power levels within 5% of the minimum are starred (**) in this situation (Fig. 13). Since both the radiation thermal resistances and local air temperatures depend on the power levels, more iterations are required before convergence is reached. Typically less than six are sufficient.

6. What Now Option List

Following a complete cycle through THERML, there are several options available to the user. A different circuit board may be analyzed either by entering the descriptive data set from the keyboard or by retrieval from mass storage. The previously recorded data set may be read in using THERML with no data checking capabilities or BOARDS may be loaded under program control to allow data checking or changes to the circuit board.

In addition the same circuit board may be reanalyzed with a new set of installation parameters, i.e., board spacing, inlet air temperature and volumetric air flow rate per board.

7. Sensitivity Analysis

Another option available allows the user to investigate the effects of various air flow rates. The user specifies a maximum air flow rate and five separate analyses are performed for each of five air flow rates up to the maximum specified. Figure 14 shows how the results of this sensitivity analysis are presented for the situation of specified power levels while Figure 15 is an output for the second situation of specified junction temperatures. The outputs from each analysis such as Figures 11 and 13 are not presented during the sensitivity analysis since the graphics mode is used but an output such as Figure 12 may be presented on the thermal printer if records of individual components are needed for each of the separate air flow rates.

A final option available to the user is termination. It is important to terminate the THERMELEX system under program control to insure normal key definitions are returned and graphics parameters correctly assigned.

III. RESULTS AND CONCLUSIONS

The THERMELEX system offers the designer of electronic circuit boards the means to predict the thermal performance of air cooled circuit boards and avoid the problems that often surface only after the equipment is in use. The system is easy to use yet provides valuable data in a variety of formats that can help the designer to make important design decisions regarding circuit board layout and/or cooling air flow parameters.

The THERMELEX system has been tested with a wide variety of circuit boards to insure that various combinations of the possible components and empty regions will create valid descriptive data sets and reasonable results. In all test cases the results have been satisfactory when compared to expected results. For example, higher component power levels result in higher junction temperatures and decreasing air flow produces higher temperatures with all else the same. Several tests were made that used the results of a power level prediction as input to the same circuit board to insure that predicted junction temperatures were the same as those specified for the original test.

In addition to the above tests for general validity, direct comparisons to experimentally determined component

case temperatures reported in reference (14) were made. The circuit board consisted of 25 equally spaced 14 pin DIPs and is depicted in Figure 6. Three different air flow rates and four different component power levels were used. The results of these experiments are shown in Figure 16. These same flow rates and power levels were used as inputs for THERMELEX and the predicted maximum case temperatures are also included in Figure 16. At the lower power levels, the agreement with the experimental results is encouraging but for the higher power levels there are significant differences. In particular, the predicted maximum case surface temperature shows a much stronger dependence on the air flow rate than the experimental results would indicate. It is believed that several effects neglected in the the thermal model become significant for low flow rates and higher component power levels. For low air flow rates, the effects of natural convection heat removal become more important, thus decreasing the actual surface temperature. In addition, at higher temperatures, the conduction into the electrical connectors and mechanical supports will also tend to hold the surface temperatures lower for the experimental results. Further work is needed to resolve the differences between the experimental results and those predicted by THERMELEX. Particular attention towards refinement of the thermal model is required.

IV. RECOMMENDATIONS FOR FUTURE WORK

While the present version of THERMELEX can be a valuable tool for predicting thermal performance of electronic circuit boards, improvements and refinements would be useful in several areas. The first recommendation would be for more experimental verification with particular emphasis towards developing better empirical heat transfer relationships for use in the present thermal model. The thermal model should also be expanded to include both the effects of natural convection and boundary conditions other than adiabatic. In particular the user should be able to specify a constant temperature for one or more of the physical circuit board boundaries. This would allow the modeling of installations that include metal card guides or cold plates.

The present model does not include the interaction that can occur between circuit boards mounted closely together. These effects could be included in the radiation sink temperatures "seen" by a board or included as effects on the local air temperature for the bottom and top of the circuit board.

Additional improvements could also be made in order to increase the number of circuit board designs that may be analyzed with THERMELEX. The limited set of components could be increased to include DIPs with different numbers

of pins and other flat pack case styles. Discrete components such as resistors, capacitors and switches are also able to transfer heat to the air stream and could also be included.

APPENDIX A

** INSTRUCTIONS FOR USE OF THERMELEX **

The THERMELEX system is designed to perform thermal analysis of air cooled electronic circuit boards. The system consists of three major programs:

1. AUTOST Driver and system setup.
2. BOARDS Input and recording of data.
3. THERML Analysis and output of results.

The AUTOST program establishes special key deffinitions and acts as the driver for the other programs within the THERMELEX system. The key deffinitions are valid throughout the system except when entering the specific component type codes during execution of BOARDS .

This driver program is entered by placing the tape in the primary tape transport (:T15) at the right side above the special keys. You then:

TYPE: LOAD "AUTOST:T15",1 Then Press EXECUTE

If the 9845A is off, the driver may be loaded by inserting the tape in :T15, latching the AUTO ST Key in the down position, and turning the power on. In either case the first question will be concerning the location of the THERMELEX system. The program will convert the default mass storage device to what ever device contains the system. It is important to not change this while using THERMELEX These instructions may be provided on paper or CRT and a paper keycode overlay may be provided as a guide to the key deffinitions that is loaded by AUTOST. A plastic overlay is available from Hewlett-Packard (part # 7120-6164) which may be filled in using the paper overlay as a guide. The other programs are entered from the option selection list(Menu) in AUTOST. Normally BOARDS is next loaded to allow the input of circuit board descriptive data from the keyboard. The instructions that follow apply to this option.

The user should have either the circuit board or a facsimile available while he is using the BOARDS program. Orient the board such that the cooling air flow is from the left to the right. Measure the length (defined in the air flow direction), width and thickness of the circuit board in millimeters (mm). It is necessary to divide the board into evenly spaced imaginary regions in both horizontal and vertical directions. The centers of each of these regions will form the nodes of a finite difference grid to be used in the thermal analysis of the electronic circuit board. The imaginary lines that are created divide the circuit board into regions that will either be empty or will contain one component. An exception to this rule is the case of 40 pin DIP's which occupy two regions due to their large size. An attempt to approximate the real circuit board with a model requires some flexibility and imagination at this point.

The thermal model used for the analysis will assume that each component is centered in the region. The following components can be included:

DIPS (horizontal or vertical)	CHIP CARRIERS
14,16,24,40 pins	16,24,40,64 pins

The limitations imposed by restricting the components to the list above will prevent some circuit boards from being precisely modeled using THERMELEX but are necessary to provide for the simple input of the descriptive data.

When BOARDS is loaded using option #1 in AUTOST a control parameter is assigned which causes the program to begin at the section which asks for the geometric parameters of the bare circuit board. You will be asked to enter the length of the board in millimeters. Enter the length using either the number pad at the far right of the keyboard or the numbers above the letter keys followed by the CONT Key. The next question will appear at the bottom of the screen while the length that was just entered will be printed immediatly below the instructions. Answer each question remembering to use the CONT Key and check the values on the screen. If a mistake is made press K0 and the program will ask the question again. After the length, height, thickness, conductivity, number of regions in the 'X' direction and the number of regions in the 'Y' direction have been entered, the program will ask for a short (less than 50 characters) descriptive title. This title will become part of the data set for the circuit board and will be used to identify the output. Two examples are:

TEST BOARD FOR PROJECT UMPTYFRATS or DESCRIPTIVE TITLE #1234.9A .

The screen will now shift from the alpha mode to the graphics mode and draw an empty board with the imaginary regions marked off with dotted lines. This picture will remain on the screen for only 3 sec after it is drawn but it may be returned to the screen using k2 to allow further time for checking. K1 will return the screen to the alpha mode for the next section.

The special function keys will now be used to input the contents of each of the regions defined on the blank board. This is the last chance to use the Back-up option (k6) if the board is not correct. A new Key code overlay will be provided if necessary and must replace the general purpose overlay on the keyboard. The keys defined in this section act as priority interrupts and will allow the screen to remain in the graphics mode as the components are defined. A flashing cross will move to each region in sucession and wait for a valid key to be pressed. Every region must be defined even if empty. It is important to wait for the cursor to move to the next empty region before keys are pressed. The back-up option will NOT work while defining components but there will be an opportunity to make corrections in the next section. When all regions have been defined, the screen will return to the alpha mode to ask if there are any corrections. At this point k2 will return the graphics to the screen and k1 will return the alpha mode to the screen.

To make corrections, the numbers of ALL incorrect regions are entered and the components erased. When there are no more to be removed, pressing CONT with no entry will allow all empty regions to be redefined. A flashing cross will visit each empty region followed by further correction opportunity as needed. When the board is correct, the general purpose key deffinitions are returned and the normal key code overlay should be replaced.

DIP components generally are produced in two different case styles, ceramic or plastic. These are different sizes and this affects the thermal analysis performed in THERML. The next section provides several methods to specify the case styles for the DIP's. These are: 1) all plastic...2) all ceramic... 3) majority ceramic (user specify which are plastic)...4) majority ceramic (user specify which are ceramic)...5) user specify case style for each DIP component. In general, option 3 or 4 require the user to input the number of regions that are either plastic or ceramic and are useful for specifying the style when when only a few are different. When there is a nearly equal mix, option 5 requires a 1 for plastic style and a 0 for ceramic style. After all DIP's are specified, a list of region numbers is displayed on the screen (in alpha mode) with the plastic cases in inverse video (numbers black on light backround) and ceramic cases in normal video. Correct as needed and again no corrections is indicated by pressing CONT Key with no entry.

The next section concerns the thermally conductive paths that are added to the circuit board. Both the electrical conductors and any thermal conduction paths or rails will transfer heat between regions. When any conduction rails are present, the effects of the electrical leads will be negligable and ignored. To aid in the modeling of the conduction rails it is necessary to introduce the concept of a Conduction Path Unit (CPU). Each of the rails is modeled as containing an integer number CPU's. The width of a CPU is defined to be .1 mm while the user must define the thickness (mm) and thermal conductivity (Watts/M-C) of the material that forms the conduction rails. The thermal conductivities of several aluminum alloys and copper are presented to aid the user. If there are no conduction rails present, the electrical lead description is entered in the much the same way; thickness (mm), average width (mm) and the conductivity (Watts-M-C). This will default to 384 Watts/M-C, the value for copper. This is the most commom material for traces on circuit boards.

In the next section the numbers of leads or CPU's that cross the interior boundaries between regions are entered. The display will alternate between the graphics and the alpha mode with the flashing cross or cursor moving to the appropriate location on the board to be defined. The graphics will remain on the screen for two seconds and then return to the alpha mode for an input line. It will ask for the input of the number of leads or CPU's between two specific regions; ie if the conduction rail is 6.7 mm wide, there are 67 CPU's in that path. Special function key 3 (F3) may be used to dump the graphics to the printer for a hard copy of the graphics picture. It is important to account for the leads on both sides of the circuit board when entering this number. As before follow all entries with the CONT key. Because of the program flow in this section, the Back_up option (k0) will not function. Do not attempt to make corrections or return to a previous section until after all entries have been made. All corrections will be made in the next section.

In the thermal model used by the THERMELEX system, all heat is transfered to the cooling air stream. None of the heat is transferred out the edges of the circuit board. For this reason, the sides of the regions at the edges will be labeled with 0 to indicate that no leads or CPU's cross this boundary. When this heat loss from the board edges and connector is neglected, the results will be conservative. These assumptions may be unacceptable for circuit boards used in installations where a significant fraction of the total heat dissipated is conducted away from the board through card guides or connectors.

When all regions have been specified, the screen will return to the alpha mode and ask if any corrections are needed. Use the special functions keys as required to either return to graphics/alpha or produce a hard copy. Enter the numbers of the connecting regions that have incorrect values for the numbers of leads or CPU's. As before, CONT with no entry signals the lack of further corrections. The physical description of the circuit board is now complete. All that remains is to specify either the component power levels (Watts) or the junction temperatures for each component.

When the maximum junction temperatures for the components are specified, the maximum steady state power level that will result in that temperature is calculated for each component. When the steady state power of each component is specified, the steady state junction temperatures are calculated. In either situation it is also necessary to specify the case to junction thermal resistance Rj_c (Deg C/Watt). The thermal model uses the component surface temperatures for heat transfer calculations and Rj_c provides the link between the component power, junction temperature and the surface temperature. If Rj_c is specified as zero (0) then the case surface temperature will be equal to the junction temperature.

After all component power levels or junction temperatures have been set, the complete list is displayed in the alpha mode to allow checking and changes. Corrections are inserted by entering the incorrect region number then entering the correct values in responce to the question asked. If desired a hard copy of all data for the circuit board will be provided from the printer.

The next section allows recording of the circuit board descriptive data on to a mass storage media. This should be done. The recorded data file may be accessed at some later time either in <u>BOARDS</u> for editing and changes or directly in <u>THERML</u> to perform the thermal analysis. <u>BOARDS</u> will create the the necessary data file to record the description but if a data file of sufficient size exists, it may be used. All old data in that file will be permanently lost. Information concerning the minimum data file size is presented by the program to help in this decision.

Built in error traps throughout the entire THERMELEX system will save the user from loss of previous inputs in case of errors. Information about the error is presented and using the error message guide on the plastic slide outs below the screen, the user may be able to make corrections. When ready, as signaled by CONT key, program flow returns to a previous point and operation resumes. The data recording section where file names are entered is particularly prone to spelling errors or entry of incorrect mass storage unit specifiers. Be careful but remember th system will attempt to catch those inevitable errors and act on them before they become fatal.

The end of a cycle through BOARDS is now complete. As the page heading that will appear states, WHAT NOW ?. More work with BOARDS is possible. The user may either input another circuit board description from the keyboard and record that to mass storage; or, he may retrieve a different circuit board descriptive data set from mass storage for checking and corrections. Another option is to perform the thermal analysis of the circuit board using the third program in the THERMELEX system, THERML.

Before an explanation of the program flow in THERML, some explanation of the use of BOARDS to edit previously recorded data files is in order. This option may be accesed through the use of AUTOST as explained on the first page of these instructions or the BOARDS program may be directly entered into the computer with the command: LOAD "BOARDS:T15,1" then Press EXECUTE

Of course the appropriate mass storage specifier should be used both here and when entering the file name for any previously recored data file. See the Operating and Programming Manual for the 9845 if the above is not clear.

Following the input of the file name that contains the descriptive data, the data file will be read and all the variables that are normally set from the keyboard will be defined. The circuit board will be drawn on the screen in graphics mode and changes to the specific components that occupy the regions may be made. However; it is not possible to change the number of regions in any way. This major revision of the board must be done as a new board input. Correction to case styles is next and then the numbers of leads or CPU's between regions will be labeled on to the graphics picture of the circuit board Changes will be allowed to the numbers but not the physical sizes of the leads or CPU's; this also requires a new board input. A list of power levels, junction temperature and case to junction thermal resistances is presented for checking and corrections as required. This edited descriptive data set may then be recorded either back to the same data file or to a new file.

There are two demonstration data files included in the THERMELEX system. DEMO-T contains a typical circuit board description needed to determine the steady state junction temperature (ie component power levels are specified). DEMO-P contains a different circuit board for which maximum powers levels are determined in the thermal analysis. The use of either of these can be helpful to familiarize the user with both BOARDS and the last program in the THERMELEX system, THERML.

THERML creates the mathematical model, performs the analysis of the circuit board and produces the output. The variables used in the thermal model are set using either a data file from mass storage or they are passed in a common block when THERML is loaded from BOARDS. There are no correction opportunities for the circuit board descriptive variables in this program.

Assuming that THERML has been loaded from the What Now option list in BOARDS, the first input is the inlet temperature(deg C) of the cooling air. After this is entered and printed on the screen, the volumetric air flow rate (M^3/sec) is requested. Since the same set of general purpose special function keys are valid in this program, the keycode overlay should remain and k0 (Back-up) may be used to return to a previous question when input errors are made. The next input is the spacing between the circuit boards for rack mounts. This spacing and the board height determines the size of the immaginary air duct containing the circuit board. When combined with the amount of air flow for each circuit board the air velocity and heat transfer correlations are determined. Since all the power dissipated on the circuit board must be removed by the air flow, it is important for these values to be as precise as possible. After the thermal analysis is complete, there will be opportunites to alter these important air flow paramters and examine the effects on the output.

Before the analysis begins, the convergence criteria must be set. The analysis consists of assuming a solution then defining a set of simutaneous equations (one for each region) which are solved for either the power or the junction temperatures. The results are compared to the previous results (the assumed values for the first itteration) and if the largest difference between these values is less than a maximum set by the user, the results are presented in graphics. If the convergence criteria is not met, the results are printed to the screen in alpha mode and another itteration is entered. The closer to zero one sets the convergence criteria, the longer the process takes. Default values for the convergence criteria are .5 Deg C or 1% change in power. These typically require 2 to 6 itterations before they are met. Each itteration takes 5 to 100 sec to perform depending on the number of regions. As the solution procedes the user may view the intermediate results to watch the progress.

The final results are written onto a picture of the circuit board with each region containing component type, junction temperature, power level and case temperature. Empty regions contain only the temperature of the circuit board. Those junction temperatures within 5% of the maximum and those power levels within 5% of the minimum are starred (**) for easy reference as trouble spots. This graphics output is automatically dumped to the printer to insure that a hard copy of the results exist.

This completes a cycle through THERML and again the question is What Now ? BOARDS may be returned to core, to make changes to the circuit board or to enter a new circuit board. Another analysis of the same circuit board may be done with a new set of air flow paramters or, a new circuit board descriptive data set may be read in from mass storage with THERML.

An additional option is sensitivity analysis. Plots of the maximum Tjunc vs. Air Flow Rate or the minimum Power vs. Air Flow Rate may be produced. A maximum air flow rate is specified and five separate analyses are performed and the results plotted and dumped to the printer. The maximum air flow rate specified should be an integer multiple of five to make for better looking axes. It is also possible to produce hard copys of the printed results for each of the air flow rates. Upon completion of this sensitivity analysis, program flow returns to the option list previously discussed.

Termination should be done under program control using the final option. This will insure that the standard key definitions are returned and that the proper graphics parameters are set for the next user of the computer.

GOOD LUCK
