Carbon dioxide (CO_2) gradients are ubiquitous and provide animals with information about their environment, such as the potential presence of prey or predators. The nematode *Caenorhabditis elegans* avoids elevated CO_2, and previous work identified three neuron pairs called "BAG," "AFD," and "ASE" that respond to CO_2 stimuli. Using in vivo Ca^{2+} imaging and behavioral analysis, we show that *C. elegans* can detect CO_2 independently of these sensory pathways. Many of the *C. elegans* sensory neurons we examined, including the AWC olfactory neurons, the ASJ and ASK gustatory neurons, and the ASH and ADL nociceptors, respond to a rise in CO_2 with a rise in Ca^{2+}. In contrast, glial sheath cells harboring the sensory endings of *C. elegans*' major chemosensory neurons exhibit strong and sustained decreases in Ca^{2+} in response to high CO_2. Some of these CO_2 responses appear to be cell intrinsic. Worms therefore may couple detection of CO_2 to that of other cues at the earliest stages of sensory processing. We show that *C. elegans* persistently suppresses oviposition at high CO_2. Hermaphrodite-specific neurons (HSNs), the executive neurons driving egg-laying, are tonically inhibited when CO_2 is elevated. CO_2 modulates the egg-laying system partly through the AWC olfactory neurons: High CO_2 tonically activates AWC by a cGMP-dependent mechanism, and AWC output inhibits the HSNs. Our work shows that CO_2 is a more complex sensory cue for *C. elegans* than previously thought, both in terms of behavior and neural circuitry.

neural circuit | behavioral choice | olfactory system | oviposition | glia

Most living matter creates temporal or spatial gradients of carbon dioxide (CO_2). Animals across phylogeny use such gradients to help detect food, conspecifics, or predators (1, 2). The ubiquity of CO_2 suggests that the ecologically relevant information it communicates will depend on the dynamics of the CO_2 stimulus and on context. CO_2-responsive excitable cells have been identified in mammals (3), arthropods (4), and nematodes (5, 6). However, the number of CO_2-responsive neurons that are functional in vivo, how they are embedded in neural circuits, and how they shape behavior is unclear.

CO_2 crosses membranes readily and dissolves to generate CO_2(aq), H^+, and HCO_3^-. Many proteins whose activity is modified by CO_2 or its solvation products have been identified. pH changes can modulate G protein-coupled receptors (7), Ca^{2+}-activated K^+ channels (8), inwardly rectifying K^+ channels (9), two pore domain K^+ channels (10), transient receptor potential (TRP) channels (11, 12), acid-sensing ion channels (ASICs) (13, 14), and Pyk2 and ErbB1/2 kinases (15). HCO_3^- modulates soluble adenylate cyclase (16) and transmembrane guanylate cyclases (17); and CO_2(aq) has been proposed to regulate transmembrane guanylate cyclases (18) and connexin 26 (19) directly. Cells expressing any of these proteins potentially could transduce changes in CO_2/H^+, raising the question: Do animals use a few specific sensory channels or a large distributed set to respond to ecologically meaningful fluctuations in CO_2? If there are many responsive neurons, how does each contribute to altered behavior or physiology?

In mammals, CO_2 levels are tightly controlled to ensure that blood pH remains stable. Peripheral sensors in the carotid bodies and incompletely defined central chemoreceptors respond to small changes in CO_2/H^+ by homeostatically altering the breathing rate (3, 20). In concert, pH and HCO_3^- sensors in the kidneys regulate H^+ and HCO_3^- excretion (21, 22). These mechanisms keep human blood pH close to 7.4, and in healthy individuals neurons experience only limited fluctuation in CO_2/H^+. In contrast, in small invertebrates such as nematodes that breathe by diffusion through a gas-permeable skin and have limited buffering capacity, CO_2 levels in body fluid probably vary more widely, according to ambient CO_2 levels.

The nematode *Caenorhabditis elegans* avoids environments with elevated CO_2 (23, 24), and high CO_2 can adversely effect its development, mobility, fertility, and aging (25). Three neurons that respond robustly to CO_2 have been identified thus far in this animal: BAG neurons that also respond to O_2, the thermosensory AFD neurons, and the gustatory ASE neurons (5, 6). CO_2 responses in BAG neurons are mediated by a receptor-type guanylate cyclase, GCY-9, that signals via a cGMP-gated ion channel encoded by the *tax-2* and *tax-4* genes (6). The CO_2 responsiveness of AFD thermosensors is sculpted by previous acclimation temperature, suggesting experience-dependent cross-modulation between temperature- and CO_2-sensing mechanisms in this neuron (26). Acute changes in O_2 also alter *C. elegans*' CO_2 responsiveness: CO_2 avoidance is suppressed when O_2 approaches 21%, because of tonic signaling by the O_2-sensing neuron URX (26, 27).

Significance

Carbon dioxide (CO_2) gradients are ubiquitous, but fluctuations in CO_2 provide an important cue shaping animal behavior. This paradox suggests that CO_2 provides contextual information that is integrated with other inputs. Here, we show that *Caenorhabditis elegans* CO_2-sensing circuits are much more sophisticated than assumed hitherto. A surprisingly large number of neurons, including nociceptors, gustatory neurons, and olfactory neurons, respond to CO_2 in vivo. Glia also exhibit large Ca^{2+} responses to CO_2. Worms therefore may couple detection of CO_2 and other cues at the earliest stages of sensory processing. Besides avoiding CO_2, *C. elegans* stops laying eggs at high CO_2. Inhibition of oviposition involves sustained activation of the AWC olfactory neurons by CO_2 and enduring inhibition of neurons innervating the egg-laying muscles.

Here, we identify many additional *C. elegans* cells that respond to CO_2, including both neurons and glia. Some of these cells probably are intrinsically CO_2 sensitive. We show that elevated CO_2 inhibits egg-laying, and tonically represses the hermaphrodite-specific neurons (HSNs) critical for normal egg-laying behavior. CO_2 inhibition of egg-laying involves the AWC olfactory neurons, which are persistently stimulated at high CO_2 by a cGMP-dependent mechanism.

Results

Several CO_2-Evoked Responses Do Not Require Previously Identified CO_2 Sensors. Only one chemosensory transducer of CO_2 has been identified in *C. elegans*, GCY-9, which is required for CO_2 sensitivity in BAG neurons (6). The inherent complexity of CO_2 as a stimulus and the numerous molecules whose activity is sensitive to CO_2/H^+ in vitro (3) led us to conjecture that *C. elegans* has undiscovered CO_2-sensing neurons and pathways. To investigate this possibility, we examined CO_2-evoked locomotory responses in *gcy-9* mutants and in BAG-ablated animals, a kind gift of Manuel Zimmer, Institute of Molecular Pathology, Vienna. We placed animals on a thin bacterial lawn in a microfluidic chamber and exposed them to a 0–5–0% CO_2 stimulus train (Fig. 1). Animals from the N2 laboratory reference strain responded to rising CO_2 by freezing briefly, turning sharply (these turns are called "omega turns" because of their shape), and resuming forward movement with an altered course at a higher speed (Fig. 1*A*). Faster movement was maintained while CO_2 was high (Fig. 1*A*) (5). When CO_2 dropped from 5 to 0%, N2 animals transiently sped up before gradually settling (Fig. 1*A*). BAG-ablated animals and *gcy-9* mutants showed little turning during the 0–5% rise in CO_2 and failed to speed up transiently as CO_2 dropped from 5 to 0%. However, other features of the N2 locomotory response were not reduced significantly (Fig. 1 *A* and *B*). Thus, *gcy-9* and BAG neurons contribute part but not all of *C. elegans*' acute locomotory response to CO_2.

A cGMP-gated ion channel subunit encoded by *tax-4* sustains CO_2 responses not only in BAG neurons but also in AFD and probably in ASE neurons (5). Like *gcy-9* mutants and BAG-ablated animals, *tax-4(p678null)* mutants showed severe defects in turning following a 0–5% rise in CO_2 (Fig. 1*C*), as would be expected if BAG was defective. However, other features of the locomotory response to CO_2 were unaffected or even enhanced. Most prominently, *tax-4* mutants increased their speed more strongly than N2 controls at 5% CO_2 (Fig. 1*C*). This heightened locomotory arousal suggests the existence of parallel pathways that inhibit and promote rapid movement at high CO_2, whose function is impaired and intact, respectively, in *tax-4* mutants.

BAG neurons are activated not only by a rise in CO_2 but also by a decrease in O_2 (28). A set of elegant experiments has shown that activating BAG by reducing O_2 or using channelrhodopsin inhibits *C. elegans* movement (28). We speculated that tonically elevated BAG signaling at 5% CO_2 inhibits locomotion and that the transient increase in movement when CO_2 levels drop reflects disinhibition of the forward locomotion circuit resulting from a decrease in BAG activity. This scenario would explain both why *tax-4* mutants move faster than N2 worms at high CO_2 (Fig. 1*C*) and why *gcy-9* mutants and BAG-ablated animals lack the CO_2 OFF response (Fig. 1 *A* and *B*). To test the model, we expressed

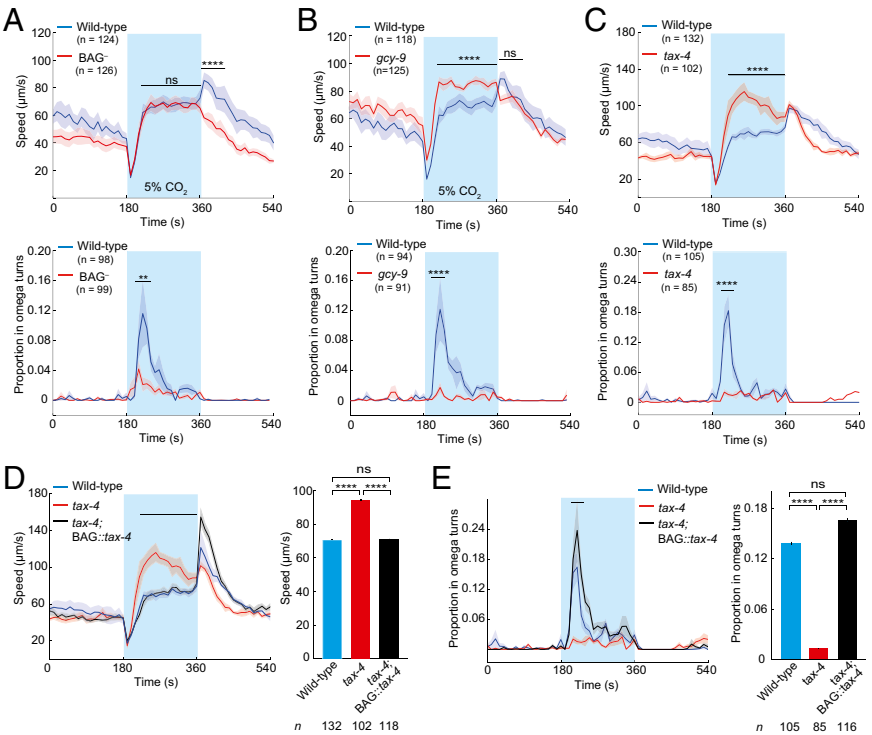

Fig. 1. A subset of CO_2-evoked changes in behavior is retained in *gcy-9* and *tax-4* mutants. (*A*–*C*) CO_2-evoked changes in speed (*Upper*) and omega turns (*Lower*) in N2 (wild-type) and BAG-ablated (BAG^-) (*A*), *gcy-9(n4470)* (*gcy-9*) (*B*), and *tax-4(p678)* (*tax-4*) (*C*) animals. Solid lines indicate the mean, and the shaded areas indicate the SEM. ****$P < 0.0001$; **$P < 0.01$; ns, not significant; Mann–Whitney *u* test. In this and all subsequent figures, black bars indicate time intervals used for statistical comparison; blue shading indicates stimulation with CO_2. Speed and omega turns were analyzed in the same set of worms. However, the exact number of animals present in the region analyzed fluctuates over time as animals leave or re-enter the food lawn. *n* refers to the number of animals in the time windows used for statistical comparisons, which differ for speed and omega turns. (*D* and *E*) Selectively expressing *tax-4* in BAG neurons using a *flp-17p::tax-4 cDNA* transgene rescues the speed (*D*) and omega turn (*E*) defects of *tax-4(p678)* mutants exposed to 5% CO_2. The background O_2 level in this and subsequent experiments is 21%.

tax-4 cDNA selectively in BAG using the *flp-17* promoter (29). This transgene restored CO_2-evoked omega turns (Fig. 1*D*) and wild-type locomotory activity at 5% CO_2 to *tax-4* mutants (Fig. 1*E*). It also conferred a larger speed OFF response than observed in N2 animals, perhaps because of overexpression of *tax-4* (Fig. 1*E*). Thus, BAG neurons promote CO_2 avoidance by stimulating turning when CO_2 rises and also slow down dispersal from high CO_2 by inhibiting rapid movement at high CO_2. Moreover, the striking locomotory response of *tax-4* mutants to CO_2 implies that there are unidentified CO_2 sensors in *C. elegans*.

Many *C. elegans* Sensory Neurons Respond to CO_2. Our behavioral data prompted us to seek other CO_2-responsive neurons by using in vivo Ca^{2+} imaging of neurons expressing the ratiometric sensor YC3.60. We detected robust CO_2-evoked Ca^{2+} increases in the nociceptive ADL and ASH neurons, the food/pheromone-sensing ASK neurons, the AWC olfactory neurons, and the ASJ photoreceptors/pheromone sensors (Fig. 2*A*). As a notable exception, YC3.60 reported that the ASG gustatory neurons were not activated but were slightly inhibited by CO_2. The majority of the CO_2-responsive neurons we identified exhibited a Ca^{2+} transient followed by a tonic component that decayed partially or completely within the 3-min window of stimulation. Interestingly, CO_2 responses in the AWC neurons deviated from this pattern: The relatively slow Ca^{2+} rise showed no sign of decay over our 3-min recording, reminiscent of the CO_2 response reported in the ASE gustatory neurons (5).

These imaging results were unexpected, especially because previous studies failed to detect CO_2-evoked Ca^{2+} responses in the nociceptive ADL (6) and ASH neurons (5, 6). Such discrepancies may reflect differences in stimulus regimes, imaging conditions, Ca^{2+} indicators, or transgenic lines used. In the case of ASH, the differences between our results here and in a previous study (5) appear to be associated with the transgenic imaging lines used.

A potential confound in using cameleon or GCaMP sensors to measure CO_2-evoked responses is the pH sensitivity of fluorophores (30). Acidification caused by a rise in CO_2 could alter the fluorescence signal from Ca^{2+} sensors independently of changes in Ca^{2+}. In vitro, the fluorescence of YC3.60 fluorophores is pH resistant (31). Nevertheless, to control for this possibility in vivo, we generated a Ca^{2+}-insensitive derivative of YC3.60 by mutating its Ca^{2+}-binding sites (*Methods* and Fig. S1), expressed the probe in the AWC, ASJ, and ADL neurons, and imaged CO_2 responses. In none of these cells did we observe a CO_2-evoked increase in the YFP/CFP fluorescence ratio, contrasting with our results using wild-type YC3.60 (Fig. S1). Our data suggest that ADL, ASH, ASJ, ASK, and AWC sensory neurons are all CO_2 responsive.

How is complexity at the sensory level represented in downstream interneurons? Many of the CO_2-responsive neurons we have identified, including ASE, ASH, ASK, ADL, and AWC, make synaptic connection onto the AIA interneurons. Previous studies suggest AWC, ASH, and ASK inhibit AIA (32, 33)

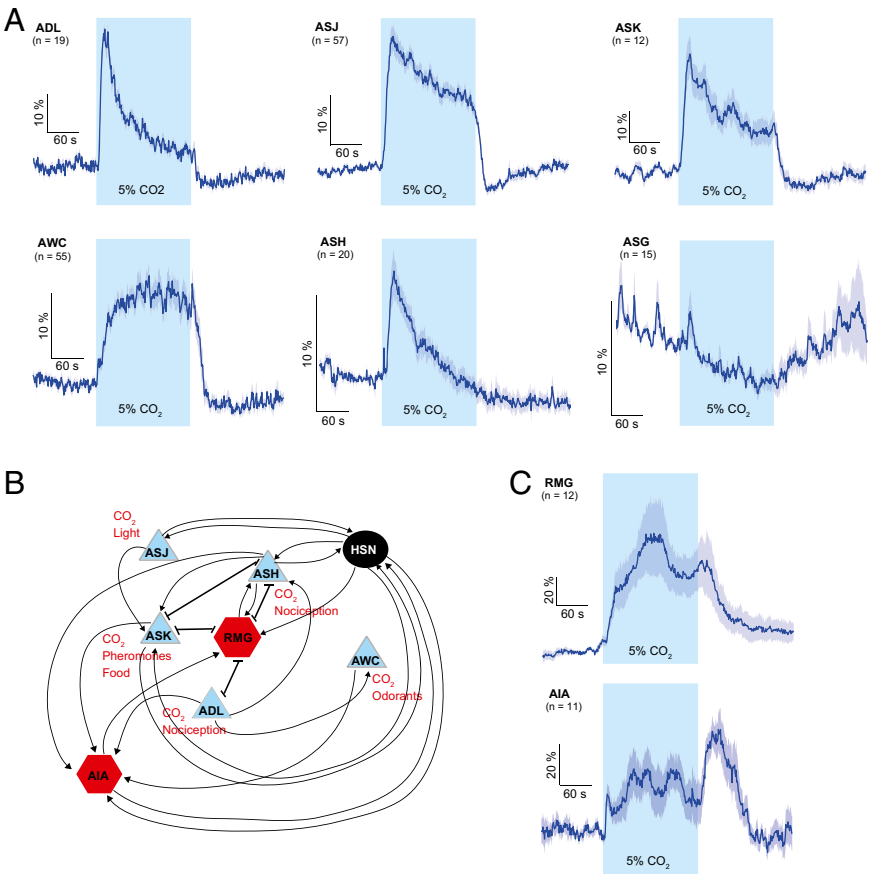

Fig. 2. Many *C. elegans* neurons show CO_2-evoked Ca^{2+} responses. (*A*) Averaged Ca^{2+} responses of sensory neurons to a 5% CO_2 stimulus measured using YC3.60. Each blue trace represents the average percentage change in R/R_0 for the indicated neuron, where R is the fluorescence emission ratio at a given time point and R_0 is its initial value. The shaded region indicates the SEM of the mean response. (*B*) Circuit diagram showing connections between newly identified CO_2-responsive neurons and two major downstream interneurons, AIA and RMG. (*C*) CO_2-evoked Ca^{2+} responses in RMG and AIA interneurons. Individual traces are plotted in Fig. S2.

whereas ASEL inputs probably are excitatory (34). A rise in CO_2 evoked a rise in AIA Ca^{2+}, consistent with excitatory input (Fig. 2*C* and Fig. S2*A*). Removal of the CO_2 stimulus, however, evoked a transient further rise in Ca^{2+}, which is explained most easily as a disinhibitory response, before Ca^{2+} returned to baseline (Fig. 2*C* and Fig. S2*A*). These data suggest that CO_2 responses in AIA interneurons reflect compound excitatory and inhibitory inputs, although we have not attempted to map how individual sensory neurons contribute to the CO_2-evoked Ca^{2+} responses in AIA.

CO_2 Evokes a Persistent Ca^{2+} Drop in Glial Sheath Cells of Amphid and Phasmid Neurons. In mammals astrocytes in the retrotrapezoid nucleus respond to CO_2/H^+ and probably contribute to respiratory drive when CO_2 levels increase by releasing ATP (35, 36). Astrocytes are glia and can have multiple functions, including provision of nutrients, maintenance of extracellular ion balance, and in some cases release of neurotransmitters. *C. elegans* also has glia, including sheath cells that envelop the sensory endings of chemosensory and mechanosensory neurons (37, 38). For example, the ciliated sensory endings of neurons in the major chemosensory organs of the worm, the amphids and phasmids, traverse the amphid or phasmid sheath cells in narrow membranous tubes and enter the sensillar channel within the sheath cell.

Using the YC3.60 Ca^{2+} reporter, we examined if the amphid or phasmid sheath cells respond to changes in CO_2. Both sheath cell types exhibited large and long-lasting decreases in Ca^{2+} at high CO_2, with slow ON and OFF kinetics (Fig. 3 *A* and *B*). The changes in YFP and CFP fluorescence were anticorrelated, as would be expected if they reflect FRET (Fig. 3*C*). The unusually high YFP/CFP ratio of sheath cells at 0% CO_2, even compared with stimulated ON neurons (Fig. S3*A*), suggests that these glial cells have high cytoplasmic Ca^{2+} under our imaging conditions. The sharp and sustained decrease in sheath cell Ca^{2+} evoked by high CO_2 suggests closure of Ca^{2+} channels by hyperpolarization and/or increased activity of Ca^{2+} pumps in these cells.

Previous work has shown that an ASIC channel, ACD-1, functions in amphid sheath cells to promote acid avoidance and chemotaxis to lysine (39). Whether disrupting *acd-1* or changing pH alters Ca^{2+} levels in amphid sheath cells has not been investigated. However, studies of *acd-1* heterologously expressed in *Xenopus* oocytes suggest it encodes a constitutively open Na^+-permeable channel that, unusually for an ASIC, is inhibited by protons. These data raised the possibility that sheath cell hyperpolarization at high CO_2 is caused by H^+-induced closure of ACD-1 channels. However, the CO_2-evoked Ca^{2+} response in amphid sheath cells was not altered substantially in *acd-1(bz90)* deletion mutants (Fig. S3*B*). Thus, other mechanisms must underlie this response.

AWC and ASJ Neurons May Be Primary CO_2 Sensors. Are any of the CO_2-responsive cells we have identified endogenously CO_2 sensitive, or do they respond to inputs from presynaptic CO_2 sensors? The intrinsic CO_2 chemosensitivity of BAG neurons has been established by showing that their CO_2-evoked Ca^{2+} responses are not reduced in mutants defective in synaptic transmission (5, 6) and has been demonstrated most elegantly by showing that GCY-9, a receptor guanylyl cyclase required for BAG neurons to respond to CO_2, can confer CO_2 responsiveness on a heterologous neuron (6). AFD and ASE neurons also may be primary CO_2 sensors: Their responses are not diminished in synaptic transmission mutants (5), although for AFD, which has gap junctions with AIB, we cannot exclude the possibility that gap junctions transmit CO_2 responses from presynaptic neurons. With this caveat, imaging CO_2-evoked responses in mutants defective in chemical neurotransmission can provide valuable information about the origin of the neural responses (e.g., refs. 5, 40, and 41). The AWC and ASJ neurons are thought to lack gap junctions (42), rendering direct electrical input unlikely. Both pairs of neurons responded robustly to CO_2 in *unc-13* mutants, which are defective in synaptic vesicle release (43), and in mutants of the CAPS (Ca^{2+}-dependent activator protein for secretion) ortholog *unc-31,* which are defective in release of dense-core vesicles (Fig. 4 *A–D*) (44). A mutation in *unc-64* syntaxin, which simultaneously disrupts both synaptic and dense core vesicle release, also did not diminish CO_2 responses in AWC neurons (Fig. 4*A*). These data support the notion that AWC is endogenously CO_2 sensitive. For the ASJ neurons, disrupting *unc-64* reduced CO_2-evoked Ca^{2+} responses to about 60% of the wild-type value (Fig. 4*D*). Retention of the response is consistent with ASJ being intrinsically CO_2 sensitive, but the reduced size of the response indicates that synaptic and/or neuropeptidergic input increases the response magnitude. Although these results are consistent with AWC and ASJ neurons being primary sensors for CO_2 and/or its metabolites, proving this hypothesis requires the identification of a molecular CO_2 sensor in these neurons.

CO_2-evoked responses in ASH and ASK neurons also appear not to require chemical input (Fig. S4). However, because gap junctions connect ASH and ASK neurons not only to each other but also to numerous synaptic partners, intrinsic CO_2 sensitivity cannot be inferred. One of these partners, the RMG inter/motor neuron (42), makes gap junctions to ASH, ASK, and ADL CO_2-responsive neurons (Fig. 2*B*) (42, 45). RMG Ca^{2+} increased in response to 5% CO_2 (Fig. 2*C* and Fig. S2*B*), although the responses were less stereotyped across individuals than those of the sensory neurons. We have not attempted to relate RMG Ca^{2+} responses to specific sensory neuron input.

cGMP channel subunits encoded by the *tax-4* and *tax-2* genes are expressed in four of the CO_2-responsive neurons we have identified here: ASJ, ASK, AWC, and ASG. The previously studied sensory responses mediated by these neurons [e.g., ASJ

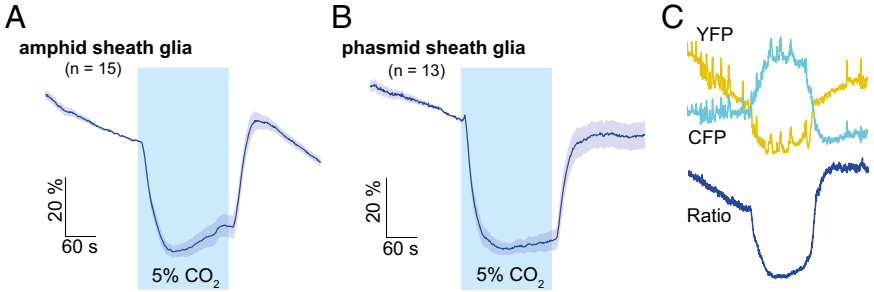

Fig. 3. Amphid and phasmid glial sheath cells are hyperpolarized by high CO_2. (*A* and *B*) Amphid (*A*) and phasmid (*B*) sheath glia exhibit a large, sustained decrease in Ca^{2+} when CO_2 levels rise. (*C*) Antagonistic changes in YFP and CFP fluorescence in phasmid sheath cells, confirming FRET.

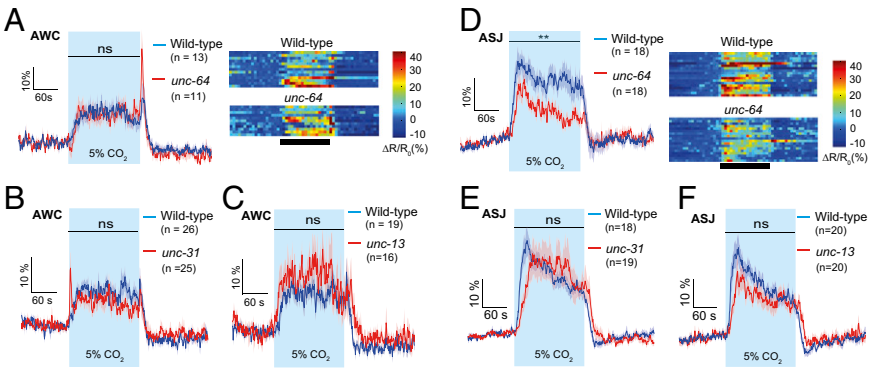

Fig. 4. Mean Ca^{2+} responses evoked by 5% CO_2 in AWC olfactory neurons (*A*–*C*) or ASJ chemosensory neurons (*D*–*F*) compared between wild-type (blue traces) and *unc-64(e246)* (*A* and *D*), *unc-31(e928)* (*B* and *E*), and *unc-13(e51)* (*C* and *F*) mutants (red traces). *unc-31* and *unc-13* animals are defective in the release of dense-core and synaptic vesicles, respectively; *unc-64* mutants are defective in both. Heat maps of the individual traces are included for *A* and *D*. ns, not significant; $^{**}P < 0.01$; Mann–Whitney *u* test. *n* = number of neurons imaged.

responses to light (46); ASK responses to pheromones and food (45, 47); and AWC responses to odors (48, 49)] are disrupted in *tax-2* or *tax-4* mutants. Do CO_2 responses in these neurons also depend on these cGMP channels? To examine this possibility, we imaged CO_2-evoked responses in ASJ, AWC, and ASK neurons in a *tax-4(p678)*-null mutant background. *tax-4* mutants retained robust CO_2 responses in ASJ and ASK neurons (Fig. 5 *A* and *B*), although, interestingly, loss of *tax-4* prevented Ca^{2+} levels in ASJ from returning promptly to baseline when the CO_2 stimulus was removed. In contrast, CO_2-evoked responses in AWC neurons were greatly diminished in *tax-4* mutants (Fig. 5*C*). Selective expression of *tax-4* cDNA in AWC using a *ceh-36* promoter fragment (50) was sufficient to restore Ca^{2+} responses in *tax-4* mutants to wild-type levels (Fig. 5 *C* and *D*). These data suggest that CO_2 sensing in AWC neurons, as in BAG neurons (5, 6), involves cGMP signaling.

The *tax-4*–independent, sustained Ca^{2+} responses of ASJ and ASK make them candidates to mediate the persistent increase in speed evoked by 5% CO_2 (Fig. 1 *A*–*D*). To test this possibility, we ablated ASJ or ASK and measured locomotory activity. However, neither disruption prevented animals from modulating their speed in response to changing CO_2 (Fig. S5).

***C. elegans* Suppress Egg-Laying in High CO_2.** How do the CO_2-evoked neural responses we have identified contribute to *C. elegans* behavior? Studies of CO_2-evoked responses have focused primarily on locomotion, either in spatial or temporal CO_2 gradients (5, 6, 23, 24). As an alternative paradigm, we examined whether CO_2 altered egg-laying behavior. We hypothesized that mechanisms should have evolved to prevent worms from exposing their offspring to adverse concentrations of CO_2 (25, 51). To test this idea, we placed individual worms on thin bacterial lawns, exposed them to either 5% or atmospheric CO_2 concentrations, and compared the number of eggs laid by each group after 2 h. Strikingly, N2 animals essentially stopped laying eggs at 5% CO_2, implying that CO_2 has an immediate and long-lasting inhibitory effect on egg-laying (Fig. 6 *A* and *B*). Because N2 worms have experienced a long period of domestication in the laboratory, we also studied the effects of CO_2 on egg-laying in the Hawaiian wild strain CB4856. Like N2 worms, these animals stopped laying eggs in high CO_2 (Fig. S6*A*).

BAG neurons are a major source of FLP-17 (FMRFamide-like peptide) peptides, which, together with FLP-10 peptides, are ligands of the G protein-coupled receptor EGL-6 (egg-laying defective) (29). Activating mutations in EGL-6 inhibit egg-laying and the HSN egg-laying motor neurons, making BAG neurons plausible candidates to mediate the inhibitory effect of CO_2. However, disrupting *gcy-9* (Fig. 6*C*) or ablating BAG (Fig. S6*B*) did not reduce the inhibitory effect of CO_2 on egg-laying. The *tax-2(p694)* promoter mutation, which disrupts CO_2 responsiveness in the BAG, AFD, and ASE sensory neurons, also did not diminish

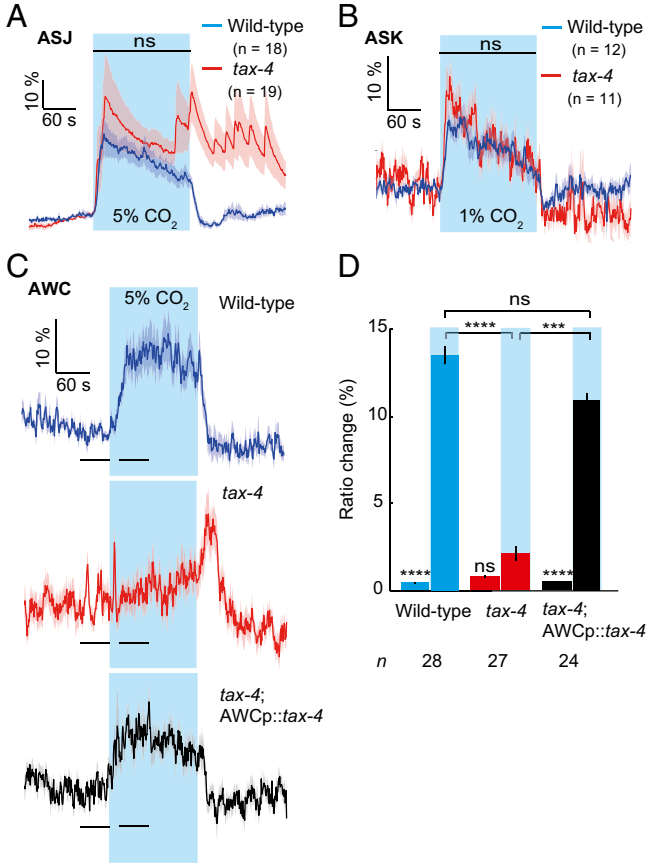

Fig. 5. TAX-4 is required cell autonomously for AWC CO_2 responses. (*A* and *B*) The cGMP-gated channel subunit TAX-4 is not required for ASJ (*A*) or ASK (*B*) CO_2 responses. Shown are average responses of *tax-4(p678)* mutants (red traces) and wild-type animals (blue traces). Note that 1% CO_2 was used to stimulate ASK. (*C*) Mean Ca^{2+} responses to 3-min stimulation with 5% CO_2 of wild-type (blue; *Top*), *tax-4(p678)* mutants (red; *Middle*), and *tax-4(p678)* animals expressing a *pceh-36::tax-4* cDNA transgene selectively in AWC (black; *Bottom*). (*D*) Quantification of data shown in *C*. Shaded areas indicate CO_2 stimulus; error bars indicate SEM. For comparisons across time intervals shown in *C*, $^{****}P < 0.0001$, $^{***}P < 0.001$; ns, not significant; Mann–Whitney *u* test.

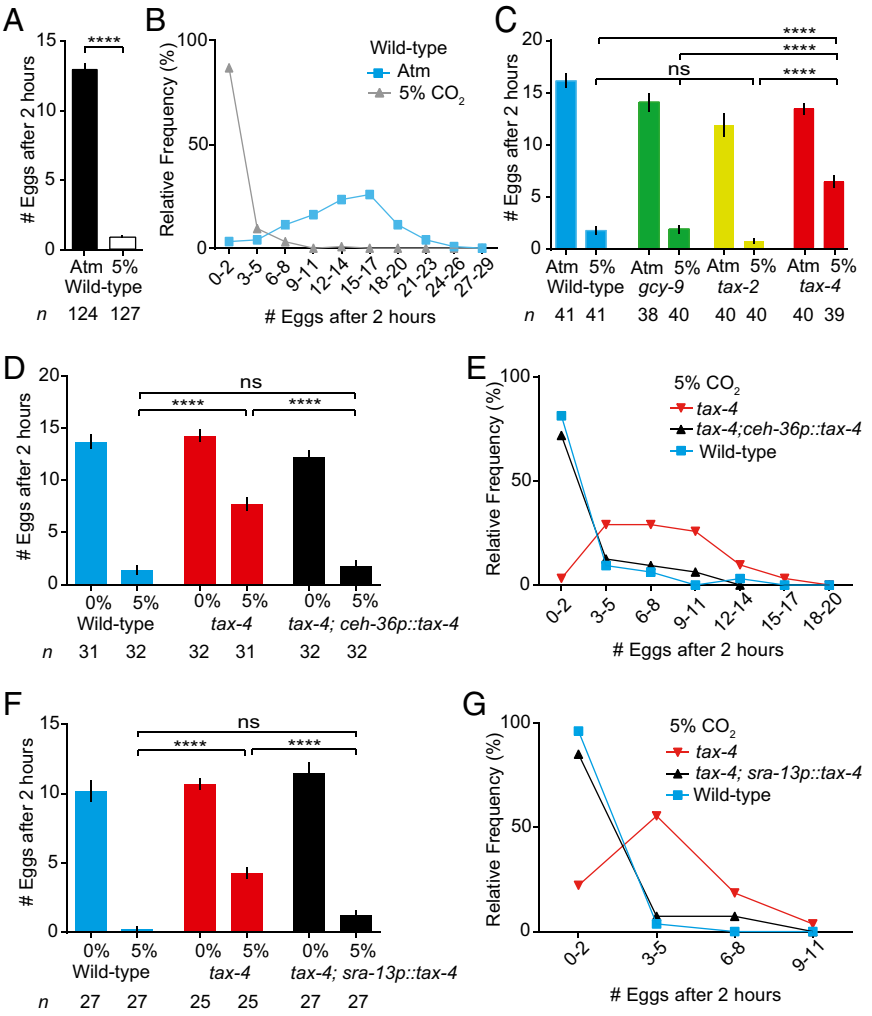

Fig. 6. CO_2 inhibition of egg-laying involves the AWC olfactory neurons. (*A*) Number of eggs laid per N2 hermaphrodite (wild-type) over 2 h by animals kept at atmospheric CO_2 (Atm) or 5% CO_2, plotted as mean ± SEM; ****$P < 0.0001$; Kolmogorov–Smirnov test. (*B*) Distribution of egg-laying frequencies; data are from *A*. (*C*) Number of eggs laid by the genotypes indicated. At 5% CO_2 *gcy-9(n4470)* mutants and animals bearing a *tax-2(p694)* promoter mutation behave similarly to N2 reference wild-type animals. A *tax-4*–null mutation, *tax-4(p678),* significantly reduces the inhibitory effect of CO_2 compared with all other genotypes. Data are shown as mean ± SEM; ****$P < 0.0001$; ns, not significant; Kruskal–Wallis ANOVA with Dunn's multiple comparisons test. (*D–G*) Expressing *tax-4* cDNA in AWC olfactory neurons using either a cell-specific *ceh-36* promoter fragment (*D* and *E*) or the *sra-13* promoter (*F* and *G*) fully rescues the *tax-4* mutant phenotype. ****$P < 0.0001$; ns, not significant; Kruskal–Wallis ANOVA with Dunn's multiple comparisons test. *E* and *G* plot the distribution of egg-laying frequencies using the data from *D* and *F*, respectively.

CO_2's effect on egg-laying (Fig. 6*C*) (5, 6). In contrast, the putative null alleles *tax-4(p678)* or *tax-2(p671)* significantly attenuated the inhibitory effect of CO_2 on egg-laying (Fig. 6*C* and Fig. S6*C*). These data suggest that one or more neurons functionally impaired in *tax-4(p678)* and *tax-2(p671)* mutants but spared in *tax-2(p694)* promoter mutants inhibit(s) egg-laying at 5% CO_2, leaving the ASG, ASI, ASJ, ASK, AWB, and AWC neurons as possible candidates (5, 48, 52). Expressing *tax-4* cDNA under the control of the *sra-13* promoter, whose expression pattern overlaps with that of *tax-4* only in AWC neurons (53), or under an apparently AWC-specific *ceh-36* promoter fragment (50) fully rescued the egg-laying phenotype of *tax-4* mutants (Fig. 6*C*), just as it rescued the defects in AWC Ca^{2+} response (Fig. 6 *D–G*). These data suggest that sustained stimulation of AWC neurons by elevated CO_2 can inhibit egg-laying.

Given the *egl-6(gf)* data referred to previously (29), we speculated that, although BAG neurons are not necessary for CO_2 to inhibit egg-laying, they might contribute as part of a redundant array of CO_2 sensors. To test this hypothesis, we expressed *tax-4* cDNA selectively in BAG neurons of *tax-4(p678)* mutants using the *flp-17* promoter and examined CO_2-induced inhibition of egg-laying (Fig. S6*D*). We observed a weak but significant rescue of egg-laying inhibition. BAG neurons therefore may play a minor role in inhibiting egg-laying at high CO_2, although we cannot rule out the possibility that the small effect reflects leaky expression in AWC from the *pflp-17::tax-4* transgene.

CO_2 Tonically Inhibits HSNs. The HSNs are critical regulators of egg-laying and link the egg-laying circuit to the rest of nervous system (54). Ca^{2+} spikes in HSNs correlate with and likely trigger egg-laying events (55), because optogenetic stimulation of HSNs is sufficient to drive egg-laying (56–58). Does inhibition of egg-laying by elevated CO_2 involve inhibition of HSN motor neurons? To test this notion, we imaged Ca^{2+} in HSNs while raising CO_2 concentrations from 0 to 5%. HSNs are unusual in *C. elegans* because they spontaneously generate trains of Ca^{2+} transients (Fig. 7*A*). Upon addition of CO_2 we observed a decrease in HSN Ca^{2+} spikes that was both immediate and persistent. We also saw a general decrease in Ca^{2+} levels (Fig. 7*A*). Removal of CO_2 frequently was followed by a burst of Ca^{2+} transients in

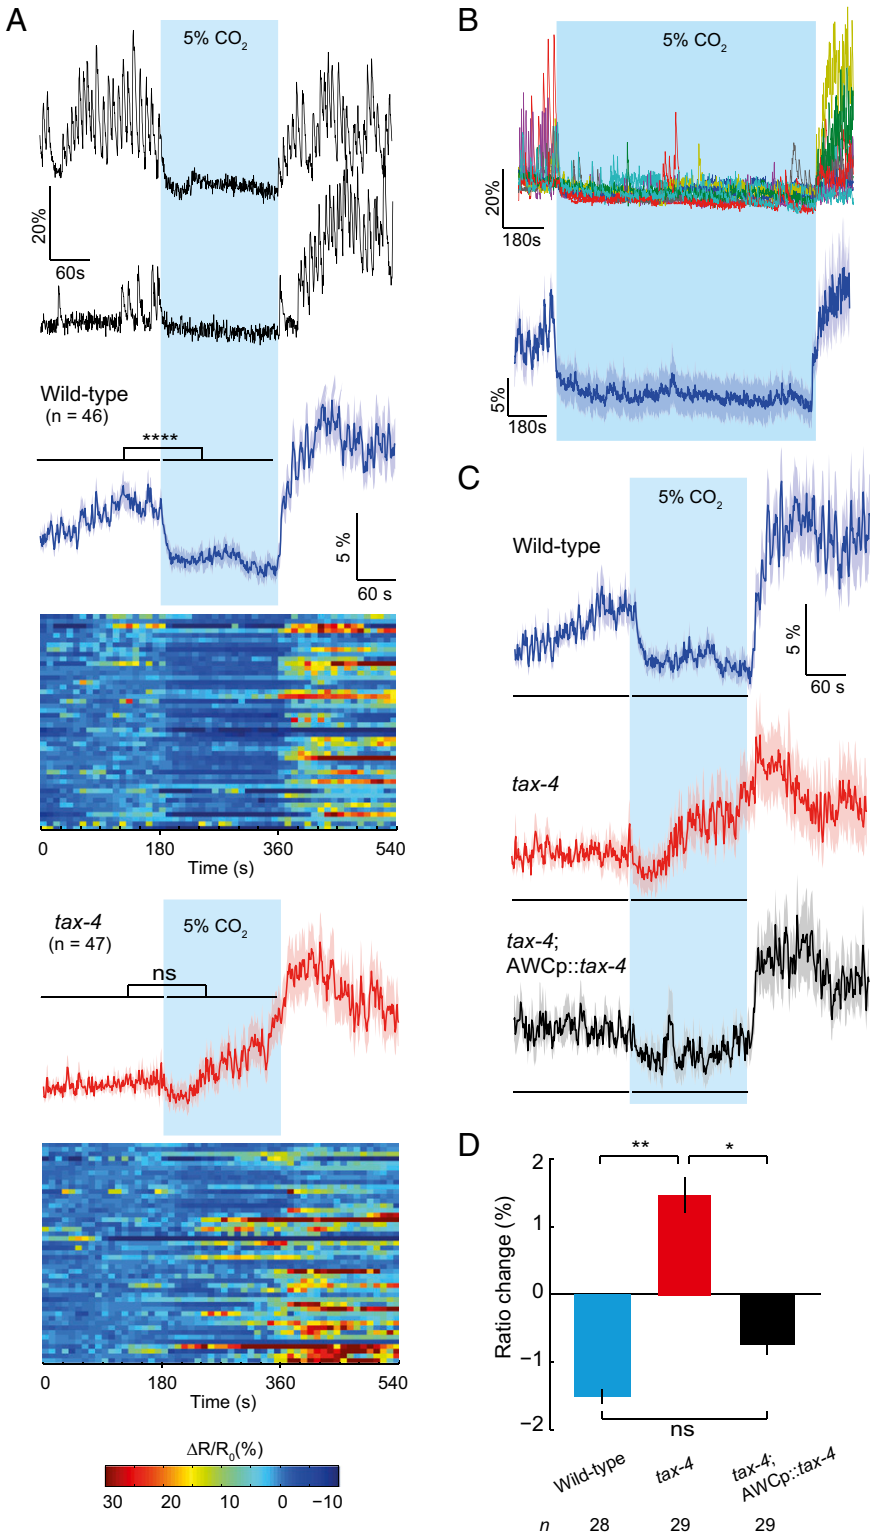

Fig. 7. HSNs are tonically inhibited by CO_2. (*A*) HSN Ca^{2+} transients are suppressed at high CO_2 in wild-type N2 (*Upper*) but not in *tax-4(p678)* mutants (*Lower*). The 5% CO_2 stimulus used is highlighted in blue. Shown are two sample traces, the average HSN response, and a color-coded pile-up of each response. ****$P < 0.0001$; Mann–Whitney *u* test; ns, not significant. Shown are the average HSN response and a pile-up of heat maps for each response. All responses are aligned to the stimulus train. (*B*) Inhibition of HSNs by elevated CO_2 persists for at least 20 min. Shown are 11 individual traces overlaid on each other (*Upper*) and the average response (*Lower*). (*C* and *D*) The *tax-4(p678)* Ca^{2+} imaging phenotype in HSN can be rescued by expressing *tax-4* cDNA in the AWC olfactory neurons. **$P < 0.01$; *$P < 0.05$; ns, not significant; Mann–Whitney *u* test.

HSNs, suggesting poststimulation rebound (Fig. 7*A*). The effects of CO_2 on HSNs, like CO_2's effects on egg-laying and AWC Ca^{2+} responses, were persistent, lasting at least 20 min with no apparent reduction in inhibition (Fig. 7*B*). These results suggest that HSNs

are inhibited in high CO_2 environments and provide a neural correlate of the striking inhibition we report at the behavioral level, consistent with HSNs' critical role in egg-laying.

AWC Responses to CO_2 Modulate HSN Activity. Do CO_2 responses in AWC inhibit HSN activity? To address this question, we first examined HSN Ca^{2+} responses to CO_2 in *tax-4* mutants. Removing *tax-4* disrupted CO_2 inhibition of HSN activity (Fig. 7 *A*, *C*, and *D*). Rescuing *tax-4* expression selectively in AWC, using a *pceh-36::tax-4* cDNA transgene, restored CO_2-induced inhibition of HSN to *tax-4* animals (Fig. 7 *C* and *D*). Together, our data suggest that elevated CO_2 elicits sustained cGMP-dependent increases in AWC Ca^{2+} levels that tonically depress HSN activity, inhibiting egg-laying while CO_2 remains high.

Because AWC-dependent olfactory responses involve the AIA interneurons (32), we asked if AIA is required for *C. elegans* to inhibit egg-laying at high CO_2. AIA-ablated animals robustly suppressed egg-laying at 5% CO_2, suggesting that this neuron is not essential for this behavior (Fig. S6*E*).

Discussion

C. elegans has an unexpected richness of CO_2-responsive cells. In addition to the previously identified BAG, AFD, and ASE neurons, the AWC olfactory neurons, the ASJ and ASK gustatory neurons, the ASH and ADL nociceptive neurons, and the amphid and phasmid glial sheath cells all respond to CO_2. AWC and ASJ may be intrinsically CO_2 sensitive: These neurons lack anatomically defined gap junctions (42), and their CO_2 responses are retained in mutants with defects in both synaptic and dense core vesicle release. Odor and CO_2-responses in AWC both involve cGMP signaling. However, although AWC is activated by the removal of attractive odors (59), it is a rise in CO_2 that activates AWC.

Our search for CO_2-sensing neurons was not exhaustive, and there is no reason to assume that CO_2 responsiveness is restricted to the neurons we have identified. Recent developments in imaging methods may facilitate a more complete description of the functional circuitry underlying the detection of CO_2 (60, 61).

CO_2 Inhibition of Egg-Laying. The choice of oviposition site is an ecologically important decision with a direct impact on species fitness. Other than having a clear preference for laying eggs on food and avoiding laying eggs in high osmolarity and in the presence of vibrational stimuli (55), how *C. elegans* choose oviposition sites is unknown (54). We show that *C. elegans* strongly and persistently inhibits egg-laying in 5% CO_2, even when food is present. The AWC olfactory neurons contribute to this inhibition, but other neurons are involved also. Previous work has shown that ablating the AWC and ASK neurons partially disrupts the stimulatory effect of food on egg-laying (62). Ca^{2+} imaging suggests that food-associated cues inhibit the AWC and ASK neurons (47). Perhaps the CO_2-evoked Ca^{2+} increases we observed in these same neurons antagonize the effects of food on ASK and AWC neurons, thereby inhibiting egg-laying.

The effects of CO_2 on egg-laying involve the HSNs, which are thought to be the executive neurons driving egg-laying events (55, 63). High CO_2 persistently inhibits HSN activity. HSNs exhibit spontaneous activity that does not require extrinsic neuronal input events (55). CO_2 inhibits this intrinsic activity, partly as a result of AWC signaling. CO_2 has been shown to regulate oviposition in several insect species, although the mechanisms involved are not understood (1).

A Large Network of Multimodal Neurons Responds to CO_2. Each of the CO_2-responsive neurons we have identified mediates responses to other sensory cues in addition to CO_2. Multimodal sensory neurons may be the norm rather than the exception in *C. elegans*. Nevertheless, the number of sensory neurons responsive to CO_2 is unusual and suggests that worms can integrate the detection of CO_2 and other cues at the earliest stages of sensory processing. Analogously, olfactory neurons in mice that respond to CO_2 are also exquisitely sensitive to the peptide hormones uroguanylin and guanylin, natural urine stimuli, as well as the volatile semiochemical carbon disulfide (64, 65). These sensors are different from the olfactory sensors initially identified in the fly that respond only (or primarily) to CO_2 stimuli (66), and this finding suggests that both worms and mice can couple the detection of CO_2 to that of other sensory cues within multimodal neurons, perhaps as an efficient strategy to glean information from a generic cue such as CO_2 (67).

Glial Cell Responses to CO_2. Amphids and phasmids are the main chemosensory organs of nematodes. Amphids contain the ciliated sensory endings of 12 chemosensory and thermosensory head neurons; phasmids contain endings of two ciliated sensory neurons. Amphid and phasmid sheath cells envelope a significant part of the sensory endings of these neurons but lack synaptic connections or gap junctions with them (www.wormatlas.org/hermaphrodite/neuronalsupport/Neurosupportframeset.html). Whether the large and persistent changes in Ca^{2+} evoked in the glial cells by CO_2 are intrinsically generated or reflect neuronal input, e.g., by volume transmission, is unclear. Moreover, it is tempting to speculate, based on their physical intimacy, that glial sheath cells could communicate with sensory neurons nonsynaptically, by ephaptic coupling, either through the exchange of ions or as a result of local electric fields (68, 69). It will be interesting to explore if the glial CO_2 responses influence neuronal CO_2 responses, or vice-versa.

Functional Significance of Complexity. What is the functional significance of having so many CO_2-responsive cells? Different CO_2-responsive neurons have different response characteristics: They can be transient or persistent and ON or OFF. Different neurons also appear to make different contributions to CO_2-evoked behaviors, depending on the exact behavior(s) studied, the experimental paradigm used, and previous experience (5). *C. elegans* thrive on rotting plant material and in microbe-rich habitats (70) where CO_2 concentrations likely vary substantially. Rather than having a single sensory channel that links the perception of CO_2 to a hard-wired behavioral response, the availability and context-dependent use of multiple sensors could allow greater behavioral flexibility. As in *C. elegans*, a variety of CO_2-responsive neurons have been identified in the mouse brain (3). Part of this complexity reflects different neurons controlling different CO_2-evoked responses, e.g., control of breathing rate or of animal arousal. Part may have evolved to enable very small changes in CO_2/H^+ to alter the breathing rate adaptively in a highly reliable way.

In flies, CO_2 sensing initially was thought to depend on a dedicated olfactory circuit that mediates detection and innate avoidance of CO_2 (66), consistent with a labeled line-coding logic. Later work showed that avoidance of higher CO_2 concentration requires an additional, functionally segregated population of olfactory receptor neurons that likely detect CO_2-induced acidosis (71). However, flies also can exhibit behavioral attraction to CO_2 mediated by the gustatory system (72), suggesting different behaviors can be generated in different contexts by using different modes of sensory detection. The emerging pattern is that a plethora of sensory structures and cells are sensitive to CO_2, endowing animals with greater behavioral flexibility and the capacity to integrate information from multiple sources.

A future challenge is to identify the sensor molecules mediating the CO_2 responses we have described. Doing so will distinguish unambiguously between intrinsically CO_2-sensitive neurons and their downstream targets. In vertebrates the majority of CO_2-sensitive structures appear to detect changes in pH rather

than molecular CO_2 or bicarbonate (but see refs. 19 and 73). The sensory molecules implicated in these responses are diverse and include PKD2L1 and TRPA1 channels mediating gustatory and noxious responses to CO_2 (74) and acid-sensing ion channels (ASIC1A) expressed in the amygdala and bed nucleus of the stria terminalis to elicit CO_2-evoked fear responses in mice (14, 75). In addition, a variety of receptor molecules have been proposed to underlie CO_2 chemosensitivity in peripheral and central chemoreceptors essential for the control of respiration (76–78). Some of these molecules are expressed in the nervous system of the worm, including members of the TRP channel superfamily, ASICs, and inward rectifier (Kir) potassium channels (79). They may have similar roles in CO_2 sensing in *C. elegans*. At a circuitry level, we need to understand how the members of the remarkably extensive network of CO_2 responsive neurons cooperate or compete to drive behavioral responses. From an evolutionary perspective, such a network may facilitate behavioral diversification during speciation.

Methods

Strains. Strains were grown at 22 °C under standard conditions with *Escherichia coli* OP50 (80). A full strain list is provided in *SI Strain List*.

Behavioral Assays.

Locomotory responses. Assays were performed essentially as described previously (5). Briefly, 20–25 adult hermaphrodites were picked to NGM plates seeded 16–20 h earlier with 20 μL of *E. coli* OP50 grown in 2× TY medium (per litre, 16 g tryptone, 10 g yeast extract, 5 g NaCl, pH 7.4). To create a behavioral arena with a defined atmosphere, we placed a 1 cm × 1 cm × 200 μm deep polydimethylsiloxane chamber on top of the worms, with inlets connected to a PHD 2000 Infusion syringe pump (Harvard apparatus), and delivered humidified gas mixtures of defined composition at a flow rate of 3.0 mL/min. We recorded movies using FlyCapture on a Leica M165FC dissecting microscope with a Point Gray Grasshopper camera running at two frames/s. Movies were analyzed using custom-written Matlab software to detect omega turns and reversals and to calculate instantaneous speed.

Egg-laying assays. L4-stage animals were picked onto plentiful food and grown under standard conditions for 36–38 h. Individual worms then were transferred to a square-shaped bacterial lawn seeded the night before with 40 μL of *E. coli* OP50 grown in 2× TY. Assay plates were placed into a gas-tight chamber containing 5% CO_2, and controls were placed next to the chamber and otherwise treated identically. For each genotype and condition we assayed six to eight animals on each of at least three different days. After 2 h, worms were removed from the assay plate, and the number of eggs laid by each animal was counted. We used Prism 6 (GraphPad) for statistical analysis and to plot data.

For rescue experiments, nontransgenic siblings were used as controls in all experiments.

Ca^{2+} Imaging. Ca^{2+} imaging of immobilized animals was performed as described previously (5, 81) using an inverted microscope (Axiovert; Zeiss), a 40× C-Apochromat lens, and MetaMorph acquisition software (Molecular Devices). Worms were glued to agarose pads (2% in M9 buffer, 1 mM $CaCl_2$) using Dermabond tissue adhesive with the nose and tail immersed in a mix of OP50 and M9 buffer. Recordings were carried out at two frames/s with an exposure time of 100 ms in all experiments. Photobleaching was minimized using optical density filter 2.0 or 1.5. An excitation filter (Chroma) restricted illumination to the cyan channel, and a beam splitter (Optical Insights) was used to separate the cyan and yellow emission light. A custom-written Matlab script was used to analyze image stacks and obtain statistics.

Molecular Biology and Generation of Transgenic Lines. Expression constructs were made using the MultiSite Gateway Three-Fragment Vector Construct Kit (Life Technologies). Promoters used in this study include *sra-9* (3 kb; ASK), *sre-1* (4 kb; ADL), *trx-1* (1 kb; ASJ), *ceh-36* (334 bp; AWC), *ops-1* (1.98 kb; ASG), *flp-21* and *ncs-1* (RMG), *gcy-28d* (2.98 kb; AIA), *fig-1* (2.2 kb; glia), sra-6 (3 kb; ASH), *odr-1* (AWC), *sra-13* (AWC), and *cat-1* (HSN). The *ceh-36* delta promoter was a kind gift from P. Sengupta, Brandeis University, Waltham, MA. The HSN imaging line driving expression of YC3.60 under a *cat-1* promoter was a gift from Robyn Branicky and Bill Schafer, MRC Laboratory of Molecular Biology, Cambridge, United Kingdom. Promoter fragments were amplified from genomic DNA and cloned into the first position of the Gateway system, genes of interest into the second position, and the *unc-54* 3′ UTR or the SL2::mCherry sequence into the third position. To generate a Ca^{2+}-insensitive version of the cameleon YC3.60 sensor (31), we mutated its three Ca^{2+}-binding sites, replacing GAG with CAA in each case (E32Q, E68Q, and E141Q). The gene was synthesized from oligonucleotides (GeneArt; Life Technologies) and cloned into the second position of the Gateway system. Rescue and imaging constructs were injected at 30–55 ng/μL, together with a coinjection marker (*unc-122::RFP* or *unc-122::GFP*) at 50–60 ng/μL.

ACKNOWLEDGMENTS. We thank Robyn Branicky, Marios Chatzigeorgiou, Changchun Chen, Dennis Kim, Josh Meisel, Birgitta Olofsson, Niels Ringstad, Piali Sengupta, Bill Schafer, Manuel Zimmer, and the *Caenorhabditis* Genetics Center (which is funded by NIH Office of Research Infrastructure Programs P40 OD010440) for strains and/or constructs and Zoltan Soltesz, Marios Chatzigeorgiou, and Robyn Branicky for invaluable advice and critical reading of the manuscript.
