## INFORMATION TO USERS

This was produced from a copy of a document sent to us for microfilming. While the most advanced technological means to photograph and reproduce this document have been used, the quality is heavily dependent upon the quality of the material submitted.

The following explanation of techniques is provided to help you understand markings or notations which may appear on this reproduction.

1. The sign or "target" for pages apparently lacking from the document photographed is "Missing Page(s)". If it was possible to obtain the missing page(s) or section, they are spliced into the film along with adjacent pages. This may have necessitated cutting through an image and duplicating adjacent pages to assure you of complete continuity.
2. When an image on the film is obliterated with a round black mark it is an indication that the film inspector noticed either blurred copy because of movement during exposure, or duplicate copy. Unless we meant to delete copyrighted materials that should not have been filmed, you will find a good image of the page in the adjacent frame.
3. When a map, drawing or chart, etc., is part of the material being photographed the photographer has followed a definite method in "sectioning" the material. It is customary to begin filming at the upper left hand corner of a large sheet and to continue from left to right in equal sections with small overlaps. If necessary, sectioning is continued again-beginning below the first row and continuing on until complete.
4. For any illustrations that cannot be reproduced satisfactorily by xerography, photographic prints can be purchased at additional cost and tipped into your xerographic copy. Requests can be made to our Dissertations Customer Services Department.
5. Some pages in any document may have indistinct print. In all cases we have filmed the best available copy.

## INTRODUCTION

Study of the mortality behavior of physical property emerged from the acceptance of the age-life relationship in depreciation estimates. For more than 200 years, statistical and actuarial methods have been used by insurance companies to analyze human mortality. The application of such techniques to determine service lives of physical property has become standard practice in regulated and unregulated industry as evidenced by a study made by the National Association of Railroad and Utility Commissioners (1943).

Depreciation Estimation

Depreciation calculations require estimates of the probable average service life of the property group or the probable average service life of the unit of property, and usually require an estimate of the probà̉le retirement aispersion pattern of a property group. Winfrey (1967, p. 12) defined probable service life and probable average. service life as:

The probable service life of an individual unit is that period of time extending from its date of installation to the forecasted date when it will probably be retired from service.

The probable average service life of a group of individual units is the average of the probable service iives of the units of the group.

Retirement dispersion pattern is determined from the distribution of the ages at retirement of the units comprising the property group.

Various systems have been devised to categorize retirement dispersions, but none has achieved the popularity of the Iowa type curves. The family of lowa type curves represents a summary of studies of the survivor characteristics of many types of industrial and utility properties. The purpose of these studies was to generalize the attrition of units of physical properties into curves representing expected trends.

Winfrey (1967) developed 18 type curve shapes which are divided into three sets based on the position of the mode of the retirement frequency curve with respect to the average service life: six left modal, seven symmetricai, and five right modal. Couch (1957) categorized three curves whose mode is at or very near the origin and a straight line survivor curve. All four of these curves were designated origin modal. Subsequent research in industry has produced nine other type curves by combining the retirement frequency curves of the original Iowa type curves to form a new curve. There now exist 31 Iowa type curves.

Over forty years have passed since the lowa type durves were compiled and published by Winfrey. In the past questions have been raised among the utility industry as to whether the Iowa type curves are still valid representations of mortality
characteristics. A study by Russo (1978) repeated the same process of data collection and analysis performed by Winfrey. The clustering patterns Russo developed from the data gathered were found to be no better than the original Iowa type survivor curves.

The collection of data and subsequent statistical analysis are the fundamental tools for predicting service lives of physical property and retirement dispersion patterns. Edison Electric Institute (1952) cautions the depreciation analyst that the plant installed today or in general use may bear little or no resemblance to plant being retired or which has been retired. Hence, there is another important component of depreciation estimation which is described by Winfrey (1967, p. 9):

> While the author strongly recommends the development and use of the retirement data and and survivor curves as the basis of estimating the probable life of property units, he does not mean that the expert judgment should be done away with in favor of pure statistical treatment. Each individual item, each group of items, and each property or company must be dealt with in the light of its present condition, its character and amount of service production, and its relation to the present and probable future economic trends, art of manufacture, and management policies. Tables of probable service lives, type survivor curves, and statistical methods are simpiy means of recording past experience to use in predicting what the future service might be.

This investigation focuses on procedures used in life analysis which is the investigation of past experience. Life estimation seeks to predict future service lives based on informed judgment part of which is based on knowledge of past experience. The introduction of subjective factors which enter into judgment decisions is not within the empirical nature of this study.

## Life Analysis

The techniques used in analyzing plant records to determine mortality characteristics from past experience can be categorized according to the type of data required. Actuarial data are data for which the property records contain the installation date for each retirement and each survivor. Mortality characteristics determined by actuarial methods are based on relationships of aged retirements.

The other category of property one encounters is semiactuarial or unaged data. Semi-actuarial data contain records of the amount of property installed in each year, the amount of property retired each year, and the total plant balance or total survivors at all ages, with no knowledge of the age of a property unit at retirement. Semi-actuarial data is commonly found among property records for many reasons: records may have been started after the plant was installed; account classifications might have been changed within the life span
of a property; property records may be nonexistent due to acquisition, sale, or merger; and for some classes of property it may be too difficult or too expensive to maintain complete records.

Semi-actuarial data are a severe handicap in specifying both the retirement dispersion and probable average life of a property. The techniques used in analyzing semi-actuarial data are the turnover method of life analysis and the simulated plant-record (SPR) method, both of which are described by Edison Electric Institute (1952).

Turnover Method of Life Analysis

The turnover method of life analysis requires a tabulation of the annual additions, retirements, and balances over a period of years approximating the average service life or more. The usual methods of handling the data are as follows:

1) Plot the cumulative retirements and the cumulative gross additions by years from the beginning of the account.
2) Accumulate annual retirements backwards from any given date until their sum equals the balance in the account at some earlier date. The period between the two dates is the "turnover period."
3) Accumulate gross additions backwards from any given date until their sum equals the balance in the account at any given date. The period necessary for this accumulation is the indicated "turnover period."

The turnover method of life analysis provides only an indication of average service life and does not yield an indication of retirement dispersion. Winfrey (1967, p. 35) advises caution in using this method:

The average life determined will not be accurate unless the property has been continued in use at least one or two maximum life cycles, unless the replacements have about the same potential life expectancy as the retirements, and unless the property is maintained at about a constant number of service units. . . . For comparatively new properties, growing properties, and properties in which the potential lives of the units are changing rapidly, the turnover method is not to be recommended, or at least should not be used without due correction for these conditions.

These difficulties coupled with the lack of a retirement dispersion prompted the development of the simulated plantrecord method.

Simulated Plant-Record Method

To overcome the limitations of the tumnover method of life analysis, the simulated plant-record method of life analysis was introduced. The SPR method is the only procedure which yields estimates of both the probable average service life and retirement dispersion for semi-actuarial data.

To determine dispersion and average service life estimates for semi-actuarial data, the simulated plant-record method assumes a retirement distribution and average service life and that each year's additions are retired according to that
pattern. If the property did indeed experience the assumed retirement pattern, then the resulting balances from the assumed retirement pattern would very nearly duplicate the actual balances of the account. The problem is to find a distribution which most nearly duplicates the actual plant balances. The criterion most commonly used to select the appropriate retirement distribution is to pick the one which minimizes the sum of squares differences between actual and simulated plant balances.

Hill (1922a,b) developed the basic principle of the SPR method more than 50 years ago as a procedure to analyze life experience of various classes of telephone plant. Hill's method provides solutions for average service life or dispersion when the other of these two parameters is known. It is indeterminant when solving for both parameters. Subsequent research has provided for simultaneous solutions of both parameters.

Basically, the SPR method is a trial and error procedure which attempts to duplicate the annual balances (or cumulative retirements) of a plant account by distributing the annual gross additions over time according to some assumed mortality distribution. Specifically, the dollars (or units) surviving at any date are estimated by multiplying each year's additions by the successive proportion surviving at each age obtained from the assumed mortality distribution. For a given year,
the accumulation of survivors from each vintage estimates the actual plant balances for that year. This procedure is reiterated for different mortality distributions until a distribution is chosen that produces a set of simulated balances which most closely duplicates the actual balances. Most depreciation analysts use the criterion of producing a minimum sum of squares differences between the actual and simulated balances.

Bauhan (1947, 1948) developed the above procedure more than 30 years ago, and this method is the most widely used for analyzing semiactuarial data today. To aid in evaluating the selection of a representative distribution, Bauhan proposed the conformance index and the retirements experience index. The conformance index was devised to indicate the goodness of fit in relation to the size of the account and is defined as follows:

Average of Actual Balances in Conformance index $=\frac{\text { Comparison Years }}{\left(\begin{array}{c}\text { Sum of squares differences between } \\ \text { actual versus simulated balances } \\ \text { in comparison years } \div \text { number of } \\ \text { comparison years }\end{array}\right) \frac{1}{2}}$

Bauhan devised an arbitrary scale of comparison graded as: excellent for ratios over 75; good for ratios between 75 and 50; fair for ratios between 50 and 25; and poor for ratios between 25 and 0 . The lack of empirical substantiation for
this scale makes the application of the conformance index of doubtful validity.

Bauhan was concerned that the conformance index might be very high where there is little experience with the account. To correct this problem, he devised the retirements experience index which indicates the amount of experience with the account. This index is equal to the percentage of accumulated retirements of the first year's additions at that age representing the age of the account. The retirements experience index is graded on an arbitrary scale as follows: excellent for indexes over 75\%; good for indexes between $75 \%$ and 50\%; fair for indexes between $50 \%$ and $33 \%$; poor for indexes between $33 \%$ and 17\%; and valueless for indexes below 17\%. Like the conformance index, the retirements experience index is an arbitrary measure with no empirical substantiation.

Another proposed criterion was devised by white and Cowles (1972). The index of variation is defined as:

$$
\text { Index of variation }=1000 \frac{\left[\begin{array}{c}
\text { Sum of squared differences } \\
\frac{\text { from actual balances }}{\text { Number of test years }}
\end{array}\right]^{\frac{1}{2}}}{\text { Average actual balance }}
$$

The smaller the index of variation the better would be the fit of the simulated balances to actual balance. This index of variation is equal to the reciprocal of the conformance
index times 1,000. No scale to judge the quality of fit has yet been devised for the index of variation.

Variations of the simulated-plant record method have been developed by Whiton (1947) and Garland (1967). Whiton proposed the comparison of indicated retirements in place of the balances. At any date, cumulative retirements may be computed as the sum of the gross additions less the balance at that date. Both this indicated retirements approach and the balances method will select the same distribution because the magnitude of sum of squares deviations is the same for both methods. Whiton indicates the advantage of the indicated retirements approach is that for a given year the ratio of the sum of squares deviation to the cumulative retirements is greater than the ratio of the deviation to the plant balance. This, in turn, magnifies the deviation and gives a better indication of the goodness of fit.

Garland has approached the use of the retirements instead of balances in the period retirements method. This method compares actual versus simulated retirements occurring in a given time period. Specifically, the retirements occurring in a given year are computed as the difference between the beginning and ending balances plus the additions for that year. The advantage of this method according to Garland is that mortality characteristics being experienced in a recent time period are highly indicative of future retirement activity.

In the above methods, there are two underlying assumptions common to all these approaches. The first assumption is that the mortality experience of a given vintage is independent of the mortality experience of all other vintages. In other words, the occurrence of retirements from one vintage in no way affects the occurrence of retirements from any other vintage. Secondly, it is assumed that each vintage is a sample from the homogeneous population and is, hence, retired according to the same mortality distribution. Imposing these assumptions causes the SPR method to fail to detect shifts in dispersion and/or average service life between vintages.
R. E. White (1968) statistically modeled the SPR balances method and derived a test procedure in an attempt to eliminate the subjective judgment one finds in the arbitrary scales of the conformance index and retirements experience index. His method was applied by Rose (1972) and Rippe (1969) to real world data with little success. The chi-square statistic used was found to reject all but the most regular accounts.

## A STATISTICAL MODEL OF THE SIMULATED <br> PLANT RECORD BALANCES METHOD

The following statistical theory was developed by White (1968) to describe the SPR balances method.

## Derivation of Survivor Curve

Let $K$ be a discrete random variable representing the life of a unit of property where $K=\{1,2, \ldots, m\}$ and $m$ is the finite maximum life. The probability density function (PDF) of $K$ is the probability that the unit of property is retired at age $k$ or

$$
\begin{equation*}
f(k)=P(K=k)=\pi_{k} \tag{1}
\end{equation*}
$$

The cumulative distribution function (CDF) of K is the probability that the unit of property is retired before age k+1 or

$$
\begin{equation*}
f(k)=P(K \leq k)=\sum_{y=1}^{k} f(y) \tag{2}
\end{equation*}
$$

A survivor curve of $K$ may be defined as the probability that the unit of property survives through age $k$ or

$$
\theta_{0}=1
$$

$$
\begin{array}{r}
\theta_{k}=P(K>k)=1-\sum_{\bar{y}=1}^{k} f(y)=\sum_{\bar{y}=k+1}^{\sum_{\mathcal{k}}} f(y)  \tag{3}\\
(k=1,2, \ldots m m)
\end{array}
$$

$$
\theta_{m+1}=0
$$

Derivation of the Balances Method Model

To relate the survivor curve notation derived above to the balances method of the SPR, the following symbols are defined below to represent property account activity:

- $=$ a set of points in time with the same units of measure as $K$, where $T=(0,1,2, \ldots)$.
$j, k=$ points in time where $j, k \in T$.
$N_{j}=$ the number of units installed as a group at time j.
$s_{j k}=$ the proportion of units installed at time $j$ that are surviving at time $k$.
$p_{j k}=$ the proportion of units installed at time $j$ that are retired at time $k$.
$\mathrm{N}_{\mathbf{j}} \mathbf{s}_{\mathbf{j k}}=$ the number of units installed at time $j$ that are surviving at time $k$.
$N_{j}{ }^{\theta}{ }_{j k}=$ the number of units installed at time $j$ expected to be surviving at time $k$, where $\theta_{j k}=\theta_{k-j}$.
$N_{j} p_{j k}=$ number of units installed at time $j$ that are retired at time $k$.
$N_{j} \pi_{j k}=$ number of units instalied at time $j$ that are ex= pected to be retired at time $k$, where $\pi_{j k}=\pi_{k-j}$.
$B_{k}=$ total plant in service at time $k$ or $\sum_{j=1}^{k} N_{j} s_{j k}$ where $j \leq k$.

$$
\begin{aligned}
& D_{k}=\text { total plant which has been retired from time } k-1 \\
& \text { to } k=\sum_{j=1}^{k} N_{j} p_{j k} .
\end{aligned}
$$

As shown in Figure 1, the retirements for a given property account are a composite of retirements from prior vintages, each vintage successively displaced by one unit of time. In general, $D_{k}$ is equal to the sum of $N_{1} p_{1, k}, N_{2} p_{2, k}$, $\ldots, N_{k} p_{k, k}$. The total. plant in service at any time, $B_{k}$, is equal to the sum of the additions through time $k$ less the retirements through time $k$, or

$$
\begin{align*}
B_{k} & =\sum_{i=1}^{k} N_{i}-\sum_{i=1}^{k} D_{i}=\sum_{i=1}^{k} N_{i}-\sum_{i=1}^{k} N_{i} p_{i k} \\
& =\sum_{i=1}^{k} N_{i} s_{i k} \quad(i \leq k) \quad . \tag{4}
\end{align*}
$$

Using the above relationships, the expectation of any balance or any retirement may be obtained.

$$
\begin{align*}
& E\left(D_{k}\right)=E\left(\sum_{j=1}^{k} N_{j} p_{j k}\right)=\sum_{j=1}^{k} N_{j}^{\pi} \pi_{j k}  \tag{5}\\
& \mu_{k}=E\left(B_{k}\right)=E\left(\sum_{j=1}^{k} N_{j} s_{j k}\right)=\sum_{j=1}^{k} N_{j} \theta_{j k} \tag{6}
\end{align*}
$$

Thus, while the random variable $B_{k}$ denotes the actual book balance appearing in a property account, the expected value of $B_{k}$ which is equal to $\mu_{k}$ denotes a simulated balance generated by the SPR balances method.

Figure 1. Example of property account notation relating additions and retirements

The $N_{j}$ units retired at time $j$ may be viewed as $N_{j}$ independent trials where each trial can have one of several outcomes. The outcome of a particular unit or trial from $N_{j}$ may be retirement at age 1 , or at age 2 , ... , or at age $m$. Thus the number retired at time $k$ from the units installed at time $j$ ( $N_{j} p_{j k}$ ) may be described as a multinomial random variable. This distributional assumption coupled with the assumption that each vintage is subject to the same law of mortality enables derivations of variance and covariance structures for the retirements and the balances:

$$
\begin{align*}
& \operatorname{var}\left(D_{k}\right)=\operatorname{var}\left(\sum_{j=1}^{k} N_{j} p_{j k}\right) \\
& =\sum_{j=1}^{k} \operatorname{var}\left(N_{j} p_{j k}\right) \\
& =\sum_{j=1}^{k} N_{k+1-j} \pi_{j}\left(1-\pi_{j}\right)  \tag{7}\\
& \operatorname{cov}\left(D_{k} D_{k} \prime\right)=\operatorname{cov}\left(\sum_{j=1}^{k} N_{j} p_{j k} \sum_{i=1}^{k} N_{i} p_{i k}\right) \\
& =-\sum_{i=1}^{k} N_{k+1-i} \pi_{i} \pi_{k^{\prime}-k+i}  \tag{8}\\
& \operatorname{var}\left(B_{k}\right)=\operatorname{var}\left(\sum_{i=1}^{k} N_{i}-\sum_{i=1}^{k} D_{i}\right) \\
& =\operatorname{var}\left(\begin{array}{cc}
\sum_{i=1}^{k} & \bar{D}_{i}
\end{array}\right)
\end{align*}
$$

$$
\begin{align*}
& =\sum_{i=1}^{k} \operatorname{var} D_{i}+2 \sum_{i=1}^{k} \sum_{j=i+1}^{k} \operatorname{cov}\left(D_{i}, D_{j}\right) \\
& =\sum_{i=1}^{k} N_{k-i+1}\left(1-\sum_{j=1}^{i} \pi_{j}\right)\left(\sum_{j=1}^{i} \pi_{j}\right)  \tag{9}\\
& \operatorname{cov}\left(B_{k} \quad B_{k},\right)=\operatorname{cov}\left\{\begin{array}{c}
k \\
\left.\sum_{i=1}\left(N_{i}-D_{i}\right), \sum_{j=1}^{k}\left(N_{j}-D_{j}\right)\right\}
\end{array}\right. \\
& =\sum_{i=1}^{k} N_{k-i+1}\left(\sum_{j=1}^{i} \pi_{j}\right)\left(1-\sum_{j=1}^{i+k^{\prime}-k} \pi_{j}\right) \tag{10}
\end{align*}
$$

Since the values for the additions are large (usually in dollar values) the $N_{j} p_{j k}$ 's can be assumed to be normally distributed. Since each placement is independent of the others and the sum of independent normally distributed, then each balance $B_{k}$ is normally distributed.

Using these assumptions, a mean vector and variance covariance matrix are given below

$$
\begin{gathered}
\underline{B}=\left[\begin{array}{c}
B_{i} \\
B_{2} \\
\cdot \\
\cdot \\
B_{k}
\end{array}\right] \quad \underline{\mu}=\left[\begin{array}{c}
\mu_{1} \\
\mu_{2} \\
\vdots \\
\cdot \\
\mu_{k}
\end{array}\right] \\
\Sigma=E\left[(\underline{B}-\mu)^{\prime}(\underline{B}-\underline{\mu})\right]
\end{gathered}
$$

$$
=\left[\begin{array}{cccc}
\operatorname{var} \mathrm{B}_{1} & \operatorname{cov}\left(\mathrm{~B}_{1}, B_{2}\right) & \ldots & \operatorname{cov}\left(B_{1}, B_{k}\right) \\
\operatorname{cov}\left(\mathrm{B}_{1}, B_{2}\right) & \operatorname{var} \mathrm{B}_{2} & & \\
\cdot & & \\
\cdot & & \operatorname{var} B_{k}
\end{array}\right]
$$

The vector of balances $\underline{B}$ has a multivariate normal distribution with mean $\mu$ and variance-covariance matrix $\sum$. Furthermore the quadratic form $z=(\underline{B}-\underline{\mu}) \Sigma^{-1}(\underline{B}-\underline{\mu})$ ' is a $\chi^{2}$ variate with $k$ degrees of freedom. Hence the null hypothesis that $B$ did in fact come from a multivariate normal distribution with mean $\underline{\mu}$ and covariance matrix $\Sigma$ may be tested by calculating the $X^{2}$ statistic $z$.

White and Cowles (1970, p. 1207) formulated the null hypothesis to be tested in the following manner:

> The actual balances came from the parent population described by the distribution of simulated balances, clearly, if it can be established with some level of certainty that the book balances did come from the same population as those of the simulated balances, then the mortality distribution used to derive the simulated balances can be accepted with the same level of certainty to be descriptive of the mortality characteristics of the account.

White (1968) met with limited success in attempts to apply the chi-square statistic to real and simulated data. For all but the most regular accounts, the chi-square statistic was too powerful and rejected the dispersion which produced the minimum sum of squares differences between actual and
simulated balances. These difficulties prompted an investigation of tolerance regions.

Tolerance Regions

Chew (1966) defines a tolerance region as a region $R$ which can be constructed such that the probability is $\gamma$ that R contains at least (100P) \% of the individuals in the population or such that the average or expected value of the proportion of the population contained in $R$ is exactly (100p)\%. This construction of a tolerance region is equivalent to finding a test function for the hypothesis testing problem. The tolerance region may take on different shapes. Two are examined in this research: the ellipsoidal shape and the rectangular parallelepiped shape.

By comparing results given by Chew (1966) and Fraser and Guttman (1956), is is evident that the chi-square statistic derived in the previous section is equivalent to the test of hypothesis given by the ellipsoidal shape. The rectangular parallelepiped shape is given below as derived by Chew (1966). Let
$P=$ the proportion of the population in the tolerance region.
$\mathrm{p}=$ the number of comparison years or the number of dimensions in the population.
$z(\alpha)=$ upper $100 \alpha$ percent point of the standard normal distribution.

To form a rectangular parallelepiped region, the vari-ance-covariance matrix for the balances must be diagonal, so a vector $\underline{y}$ must be found such that $\underline{y}=A B$ and $\Sigma_{Y}=A \Sigma_{B} A^{\prime}$ is diagonal. Since $\Sigma_{B}$ is a real symmetric matrix, $A$ will be the matrix of eigenvectors of $\Sigma_{B}$, and the nonzero elements of $\Sigma_{y}$ will be the eigenvalues of $\Sigma_{B}$. Thus the $\mu_{i}$ and $\sigma_{i}$ values in formula (11) pertain to $y$. The tolerance region formula for a rectangular parallelepiped region is:

$$
\begin{gather*}
\operatorname{Pr}\left\{\mu_{i}-z\left(\frac{1}{2}-\frac{1}{2} P^{1 / p}\right) \sigma_{i} \leq y_{i} \leq \mu_{i}+z\left(\frac{1}{2}-\frac{1}{2} p^{1 / p}\right) \sigma_{i}\right\} \\
=p^{1 / p}  \tag{11}\\
i=1,2, \ldots p
\end{gather*}
$$

Because the y's are uncorrelated, the probability that all $p$ statements are true is $P$. By varying the values for $P$, it was hoped that the rectangular parallelepiped region would be less powerful than the chi-square statistic and allow acceptance of more accounts.

## OBJECTIVES

The simulated plant record method has been the subject of great controversy in its application and analysis. The statistical model developed by White (1968) was an attempt to have a basis of comparison which was empirical in nature rather than subjective such as the conformance index or retirements experience index. To gain further understanding of statistically modeling the SPR method, this investigation has been undertaken.

The specific objectives of this study are as follows:

1. To examine the normality assumptions which underlie the statistical theory of the SPR method.
2. To determine the effect the shape of the tolerance regions used has on conclusions reached.
3. To examine modifications in statistical theory when the data are dependent on what occurred in previous years.
4. To develop a procedure by which data-dependent cases can be examined using independence assumptions.
5. To determine the effectiveness of the balances method in estimating the correct dispersion and service life.
6. To develop computer programs which aid in implementation of the objectives above.

This study is restricted to examination of the balances method. Since the balances method is the most popular approach used by depreciation analysts and it can be represented in a statistical manner, scrutiny will be given to this approach.

MONTE CARLO STUDY WITH CONSTANT ADDITIONS

In evaluating the effectiveness of a particular technique or methodology, the results must be compared against an acceptable standard. Real data are affected by many inputs only a few of which can be isolated. The importance of the inputs is usually impossible to ascertain. These inputs and their relative importance will vary with time as unforseen forces act upon them, making it impossible to observe the effect of any single factor held constant over time. The introduction of inflation into the analysis, for example, would cause accounts whose units are expressed in dollar values to have units of varying value, introducing even more complexity into the situation.

To aid in controlling the inputs of an account, a Monte Carlo study was undertaken to determine if the normality assumption of the balances upon which the statistical development rests is valid and what effects, if any, are involved when the shape of the tolerance region is changed. In generating the samples for the Monte Carlo study, the PGM program documented by Erbe (1971) was used.

Description of PGM Computer Program

The PGM is capable of simulating the life of a property account over a period of years. This program provides the
option of either an expected value or a random value simulation. In the expected value simulation, the age frequency distribution of simulated retirements from each vintage will conform exactly to the smooth retirement frequency curve of the specified population. In the random value, an age frequency distribution will be produced that deviates about the expected values of a smooth retirement frequency curve.

Input variables include an average price per unit installed and a variable range above and below the average price. In simulating the retirement experience of an account, the initial placement and a desired growth rate are specified. The annual placement in succedding years is computed to maintain a specific growth in the plant balance. For each simulation year, the effective growth rate is sampled from a normal distribution with a mean of the specified growth rate and a standard deviation of $10 \%$ of the stated mean.

The decision rule used by the PGM to determine the annual placement in succeeding years is intricate. Given the initial placement, all the units placed are retired through age $m$, where $m$ is the maximum age. In the second year, the placement is equal to the price per unit times the units that wili fetire in the second year from the initial placement divided by the percent surviving at the end of the first year taken from the assumed mortality distribution. Then all those units placed at the beginning of the second year are retired
through age m. To determine the third year's placements, the price per unit is multiplied by the units which will be retired during the third year divided by the percent surviving at the end of the first year taken from the assumed retirement distribution. The units which will retire in the third year used in the above computation are made up of retirements from placements in years one and two. In general, the placement in year $X$ is equal to the price per unit times the units which are computed to retire in year X divided by the percent surviving at the end of the first year. This decision rule has implications which will be discussed in connection with a data-dependent Monte Carlo study.

For the special case where a constant number of additions is added each year, there is a special option register which overrides the computation of additions to meet a specific balances but computes retirements as before. There is also an inflation parameter which can be used to reflect an annual price escalation.

The PGM provides the option of selecting a parent population from the original 18 Iowa type mortality curves developed by Winfrey (1967). The dispersion and average service life are assumed effective for all the time periods within the specified time span. The beginning vintage and the last vintage of the time span must be specified.

## Test of Normality for Balances

To test the distribution of the balances for the previously developed statistical theory, 100 random samples with constant additions were generated. Use of the constant infusions model assures that the assumption that the occurrence of retirements from one vintage in no way affects the occurrence of retirements from another vintage is valid.

Each of these samples came from an Iowa type Rl dispersion with a ten year average service life. Additions of $\$ 100$ were made for each year of study. No price variation nor inflation was introduced. Ten years of experience were generated. A complete listing of these samples is found in the Appendix for samples 1 through 100 inclusive.

In Figures 2 and 3, the distribution of balances in years 9 and 10 is given. From visual examination of these
 of normality is justified. To validate this distribution assumption, the chi-square goodness of fit test was applied to years five through 10. Since the additions are the same for each sample, the mean and variance in any given year are the same from sample to sample. The following means and variances as given in Table 1 can be obtained from formulas (6) and (9) applied to an Rl-10 curve with additions of $\$ 100$ per year.

Fig. 2. Distribution of balances in year 9 taken from 100 samples of an Rl-10

Fig. 3. Distribution of balances in year 10 taken from 100 samples of an Rl-10

Table 1. Means and variances for balances for the case of constant infusions

| Year | Mean | Variance |
| :---: | :---: | :---: |
| 5 | 460.55 | 35.13 |
| 6 | 540.92 | 47.99 |
| 7 | 616.28 | 66.56 |
| 8 | 685.99 | 92.33 |
| 10 | 749.42 | 117.57 |

If the normality assumption is justified, a division of each year's balances in relation to how far each balance is from the standard deviation based upon the mean would reveal an observed value of how many values fall into each class. This can be compared to expected values if the normality assumption were correct. The chi-square goodness of fit test can then be applied:

$$
\chi^{2}=\sum_{\text {all classes }} \frac{\text { (Observed Frequency-Expected Frequency) }^{2}}{\text { Expected Frequency }}
$$

with degrees of freedom equal to the number of classes minus the number of parameters being estimated.

In Table 2, the data for years 5 through 10 are broken into different classes and the chi-square goodness of fit test value given. In this case five classes have been used and two

Table 2. Frequency of balances for years 5 through 10 falling in each category and the corresponding chi-square values for samples 1 through 100

| Year | Frequency less than $\mu$ - $1.5 \sigma$ | Frequency between <br> $\mu-1.5 \sigma$ and <br> $\mu-.5 \sigma$ | Frequency between $\mu-.5 \sigma$ and $\mu+.5 \sigma$ | Frequency between $\mu+.5 \sigma$ and $\mu+1.5 \sigma$ | Frequency greater than $\mu+1.5 \sigma$ | Chisquare |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Expected | 6.68 | 24.17 | 38.30 | 24.17 | 6.68 |  |
| 5 | 3 | 20 | 43 | 24 | 10 | 5.13 |
| 6 | 8 | 25 | 32 | 27 | 8 | 1.92 |
| 7 | 7 | 26 | 31 | 31 | 5 | 3.90 |
| 8 | 5 | 22 | 4.5 | 22 | 6 | 2.17 |
| 9 | 6 | 19 | 41 | 29 | 5 | 2.75 |
| 10 | 3 | 30 | 33 | 30 | 4 | 6.64 |

parameters, the mean and variance, are being estimated. Hence, these values are compared to $x_{3, .05}^{2}=7.81$. For each year in question the chi-square values are less than 7.81 , so at the 5\% level of significance, the hypothesis of normality with the given mean and variance can be accepted.

The Effect of Tolerance Region Shape

Since the assumption of normality of the balances for the constant infusions case has been established, the question of how the shape of the tolerance region affects analysis will next be examined. In Figure 4, the bivariate distribution of the balances in years 9 and 10 is given. The balances in years 9 and 10 have the following mean and variancecovariance structure:

$$
\underline{\mu}=\left[\begin{array}{l}
749.42 \\
805.96
\end{array}\right] \quad \Sigma=\left[\begin{array}{ll}
117.57 & 105.42 \\
105.42 & 145.47
\end{array}\right]
$$

Forming the chi-square statistic

$$
\begin{equation*}
Z=(\underline{B}-\underline{\mu}) \sum^{-1}(\underline{B}-\underline{\mu}) \tag{12}
\end{equation*}
$$

for this example is equivalent to solving the equation:

$$
\begin{aligned}
& (x-749.42)^{2}(.024)-2(.018)(x-749.42)(y-805.96) \\
& +(.019)(y-805.96)^{2} \leq x_{2}^{2}, .05
\end{aligned}
$$

where $x=$ balance in year 9 and $y=$ balance in year 10.
Figure 5 shows the solution to the above equation. At the 5\% level of significance, only one sample out of 100 was rejected.

Fig. 4. Bivariate distribution of balances in years 9 and 10
for an R1-10

Fig. 5. Results of fitting ellipsoidal tolerance region to balances in years 9 and 10 from an Rl-10

The rectangular parallelepiped region involves transformation of the actual balances by premultiplying times the eigenvectors of $\sum$. In this case,

$$
\begin{aligned}
& x^{\prime}=-.75 x+.66 y \\
& y^{\prime}=.66 x+.75 y
\end{aligned}
$$

where $x$ and $y$ are defined as above. The graphical representation in Figure 6 can be compared to Figure 4 to visualize the change this transformation makes in the original data. This transformation changes the mean vector and variancecovariance structure to:

$$
\mu^{\prime}=\left[\begin{array}{c}
-32.14 \\
1100.07
\end{array}\right] \quad \Sigma^{\prime}=\left[\begin{array}{cc}
25.19 & 0 \\
0 & 237.89
\end{array}\right]
$$

Using equation (12) with $P=.95$, the rectangular parallelepiped region is given by:

$$
\begin{array}{ll}
x^{\prime}=-21.19 & x^{\prime}=-43.64 \\
y^{\prime}=1065.57 & y^{\prime}=1134.57
\end{array}
$$

rigure 7 reveals that witn the proporion of the popuiation in the tolerance region, $P$, specified to be .95 , three samples out of 100 were rejected.

The value of $P$ can be varied, but the results obtained in the rectangular parallelepiped tolerance region differ very slightly from the chi-square test. The complexity of transforming the mean and variance-covariance structure make the rectangular shape more difficult to implement. The chi-square test is the more powerful test and how it performs in other Monte Carlo studies will be the focus of later sections.

MONTE CARLO STUDIES IN A DATA-DEPENDENT SITUATION WITH NO GROWTH

One of the vital assumptions of the statistical model is that the occurrence of retirements from one vintage in no way affects the occurrence of retirements from another vintage. For the case of constant infusions, this assumption is fulfilled. However, when there are dependencies between the data during the period of study as is the case for most real world situations, the application of statistical theory assuming no data dependence causes rejection of the statistical hypothesis in most cases.

## Application of Statistical Model Assuming No Data Dependence

To test the problems that occur when events are datadependent, two Monte Carlo studies were made. In the first stuảy, 50 random samples were taken from an il Iowa type curve with a ten year average service life. 1000 units priced at $\$ 1$ each were placed at the beginning of the first year, and fifteen years of experience were generated. In the second Monte Carlo study, 100,000 units priced at $\$ 10$ each were placed in service at the beginning of the first year. The dispersion, average service life, and period of study were the same as in the first study. Both studies specified a no growih situation. After retirements occur during the first
year, the infusion is calculated so that the balance in subsequent years is as close as possible to the balance in service at the end of the first year. The decision rule used to determine the size of the infusion was discussed in the previous section. These random samples are documented in the Appendix, being samples 101 to 200 inclusive.

Examination of Table 3 reveals that in applying the statistical model the data are much more widely dispersed than theory would indicate for $\$ 1,000,000$ initial placement. Five samples out of 50 were rejected by the chi-square test at the .05 level of significance using test years $11,13,15$ for \$1,000 initial installation. For $\$ 1,000,000$ initial installation, 49 samples out of 50 were rejected by the chi-square test of hypothesis applied to test years 11,13 , and 15.

Table 3. Dispersion of the actual balances about the mean assuming no growth

| Year | Number falling outside <br> $\mu \pm 2 \sigma$ for studywith <br> $\$ 1000$ initial placement | Number falling <br> $\$ \pm, 000,000$ for <br> initi |
| :---: | :---: | :---: |
| 11 | 0 | 32 |
| 13 | 0 | 33 |
| 15 | 0 | 39 |

For the $\$ 1,000,000$ initial placement Monte Carlo study, rejection of the chi-square test in so many cases ana the
number of observations falling outside $\mu \pm 2 \sigma$ lead one to doubt that the balances are normally distributed with means and variances calculated from Equations (6) and (9). This Monte Carlo study will be the focus in the remainder of this section. A theoretical approach to the problem of data dependence will be the aim of the next subsection.

Theoretical Model for Determining the Size of the Infusion and the Mean and Variance of the Balances

A variety of decision rules can be used to determine the size of the infusion to accomplish the goal of adding enough to have the target balance in service at the end of the year. The rule used by the PGM computer program uses events which will occur in determining the amount of the addition. The development set forth here conditions events on how many units were retired from the initial placement in the first year.

The following symbols will be used.
$i=$ year of study where $i=1, \ldots, m$.
$m=$ maximum age when all units have been retired.
$\mathrm{N}=$ number of units in original installation.
$M_{i}=$ number of units installed in year $i+1$.
$X_{i j}=$ retirements that occur in year $j$ from vintage $i$.
$p_{i}=$ probability of retirement from time $i-1$ to $i$.
$\mathrm{P}=$ price per unit.
All the accounting entries will be made in dollar values.

## Size of infusion

During the first year, $N$ units are placed in service of which $\mathrm{X}_{11}$ are retired. The number of units to be added in the second year, $M_{1}$, is chosen such that the number of units left in service at the end of year 2 has expectation $N-x_{11}$ conditioned on $\mathrm{X}_{11}$, or
$E$ (Number of units left at end of year two $\mid X_{11}$ ) $=N-X_{11}$. The number of units left in service at the end of year two is equal to

$$
N-x_{11}+M_{1}-x_{12}-x_{21}
$$

$M_{1}$ is a function of some constant and multiplier times $X_{11}$, so substituting $A+B X_{11}$ for $M_{1}$, where $A$ and $B$ are unknown constants, yields

$$
N-X_{11}+A+B X_{11}-X_{12}-X_{21}
$$

We wish to solve

$$
\begin{equation*}
E\left(N-X_{11}+A+B X_{11}-X_{12}-X_{21} \mid X_{11}\right)=N-X_{11} \tag{13}
\end{equation*}
$$

Using the facts that

$$
\begin{aligned}
& E\left(X_{11} \mid X_{11}\right)=X_{11} \\
& E\left(X_{12} \mid X_{11}\right)=\left(N-X_{11}\right) \frac{p_{2}}{1-p_{1}} \\
& E\left(X_{21} X_{11}\right)=\left(A+B X_{11}\right) p_{1}
\end{aligned}
$$

and substituting in Equation (13) yields the following solutions for $A$ and $B$ :
$A=\frac{N p_{2}}{\left(1-p_{1}\right)^{2}}$

$$
B=\frac{-p_{2}}{\left(1-p_{1}\right)^{2}}
$$

Hence,

$$
\begin{equation*}
M_{1}=\left(N-X_{11}\right) \frac{p_{2}}{\left(1-p_{1}\right)^{2}} \tag{14}
\end{equation*}
$$

For the third year, solution of $M_{2}$ is similar to the above procedure. The following equation must be solved

$$
\begin{align*}
E(N- & \left.x_{11}-x_{12}-x_{13}+M_{1}-x_{21}-x_{22}+M_{2}-x_{31} \mid x_{11}\right) \\
& =N-x_{11} \tag{15}
\end{align*}
$$

Substituting in $\mathrm{M}_{2}=\mathrm{A}+\mathrm{BX}_{11}$ and use of the following results

$$
\begin{align*}
& E\left(X_{11} \mid X_{11}\right)=X_{11} \\
& E\left(X_{1 j} \mid X_{11}\right)=\left(N-X_{11}\right) \frac{p_{j}}{1-P_{1}} \quad j=2,3 \\
& E\left(X_{2 j} \mid X_{11}\right)=\left(N-X_{11}\right) \frac{p_{2} p_{j}}{\left(1-p_{1}\right)^{2}} \quad j=1,2 \\
& E\left(X_{31} \mid X_{11}\right)=\left(A+B X_{11}\right) p_{1} \tag{16}
\end{align*}
$$

produces a solution for (15):

$$
\begin{equation*}
M_{2}=\left(N-x_{11}\right)\left[\frac{p_{3}}{\left(1-p_{1}\right)^{2}}+\frac{p_{2}^{2}}{\left(1-p_{1}\right)^{3}}\right] \tag{17}
\end{equation*}
$$

In general to solve for the number of units left in service at the end of year $k$, one must solve
$E$ (Number of units left in service at end of year $k \mid X_{11}$ )

$$
\begin{equation*}
=E\left(N+\sum_{i=1}^{k-2} M_{i}+M_{k-1}-\sum_{i=1}^{k} \sum_{j=1}^{k-i+1} x_{i j} \mid x_{11}\right) \tag{18}
\end{equation*}
$$

$M_{i}$ for $i=1, \ldots, k-2$ will be previously determined quantities and $M_{k-1}$ will be solved for by substituting in $A+B X_{11}$ for $M_{k-1}$ where $A$ and $B$ are unknown constants.

The conditional expectation can be found using the following results:

$$
\begin{align*}
& E\left(x_{11} \mid x_{11}\right)=x_{11} \\
& E\left(X_{1 j} \mid X_{11}\right)=\left(N-X_{11}\right) \frac{p_{j}}{\left(1-p_{1}!\right.} \quad j=2, \ldots, k \\
& E\left(X_{i j} \mid X_{11}\right)=M_{i-1} p_{j} \\
& i=2, \ldots, k-1 \\
& j=1, \ldots, k-i+1 \\
& E\left(X_{k 1} \mid X_{11}\right)=\left(A+B X_{11}\right) p_{1} \quad . \tag{19}
\end{align*}
$$

Solutions for $M_{3}, M_{4}$, and $M_{5}$ are given below:

$$
\begin{equation*}
M_{3}=\left(N-x_{11}\right)\left[\frac{p_{4}}{\left(1-p_{1}\right)^{2}}+\frac{2 p_{2} p_{3}}{\left(1-p_{1}\right)^{3}}+\frac{p_{2}^{3}}{\left(1-p_{1}\right)^{4}}\right] \tag{20}
\end{equation*}
$$

$$
\begin{align*}
M_{4}= & \left(N-x_{11}\right)\left[\frac{p_{5}}{\left(1-p_{1}\right)^{2}}+\frac{2 p_{2} p_{4}+p_{3}^{2}}{\left(1-p_{1}\right)^{3}}+\frac{3 p_{2}^{2} p_{3}}{\left(1-p_{1}\right)^{4}}\right. \\
& \left.+\frac{p_{2}^{4}}{\left(1-p_{1}\right)^{5}}\right]  \tag{21}\\
M_{5}= & \left(N-x_{11}\right)\left[\frac{p_{6}}{\left(1-p_{1}\right)^{2}}+\frac{2 p_{2} p_{5}+2 p_{3} p_{4}}{\left(1-p_{1}\right)^{3}}\right. \\
& \left.+\frac{3 p_{2}^{2} p_{4}+3 p_{2} p_{3}^{2}}{\left(1-p_{1}\right)^{4}}+\frac{4 p_{2}^{3} p_{3}}{\left(1-p_{1}\right)^{5}}+\frac{p_{2}^{5}}{\left(1-p_{1}\right)^{6}}\right] \tag{22}
\end{align*}
$$

Equations (14), (17), (20), (21), and (22) give the decision rules to determine the number of units to be added in service at the beginning of years 2 through 6. The value in dollars of the additions would be the product of the price per unit, $P$, and the number of units placed in service in year $i, M_{i-1}$. Although it is possible to further specify the values of $M_{i}$, these results will be sufficient to examine the mean and variance structure of the balances with and without data dependence.

## Mean and variance of balances

The mean and variance structure of the balances will be different from the nondata-dependent theory developed by White (1968). Since the additions have been chosen so that the expected number alive in any year conditionea on $\mathrm{X}_{11}$ is equal to $N-X_{11}$, use of the result from Hogg and Craig (1965)

$$
\begin{equation*}
E_{Y}[E(X \mid Y)]=E(X) \tag{23}
\end{equation*}
$$

where in this case $Y=X_{1 l}$ yields

$$
\begin{equation*}
E[\text { Balance in year } k]=\operatorname{PN}\left(1-p_{1}\right) \tag{24}
\end{equation*}
$$

Let

$$
\begin{aligned}
& A_{1}=\frac{p_{2}}{\left(1-p_{1}\right)^{2}} \\
& A_{2}=\frac{p_{3}}{\left(1-p_{1}\right)^{2}}+\frac{p_{2}^{2}}{\left(1-p_{1}\right)^{3}} \\
& A_{3}=\frac{p_{4}}{\left(1-p_{1}\right)^{2}}+\frac{2 p_{2} p_{3}}{\left(1-p_{1}\right)^{3}}+\frac{p_{2}^{3}}{\left(1-p_{1}\right)^{4}} \\
& A_{4}=\frac{p_{5}}{\left(1-p_{1}\right)^{2}}+\frac{2 p_{2} p_{4}+p_{3}^{2}}{\left(1-p_{1}\right)^{3}}+\frac{3 p_{2}^{2} p_{3}}{\left(1-p_{1}\right)^{4}}+\frac{p_{2}^{4}}{\left(1-p_{1}\right)^{5}} \\
& A_{5}=\frac{p_{6}}{\left(1-p_{1}\right)^{2}}+\frac{2 p_{2} p_{5}+2 p_{3} p_{4}}{\left(1-p_{1}\right)^{3}}+\frac{3 p_{2}^{2} p_{4}+3 p_{2} p_{3}^{2}}{\left(1-p_{1}\right)^{4}} \\
& +\frac{4 p_{2}^{3} p_{3}}{\left(1-p_{1}\right)^{5}}+\frac{p_{2}^{5}}{\left(1-p_{1}\right)^{6}}
\end{aligned}
$$

These $M_{i}$ can be represented as

$$
\begin{equation*}
M_{i}=A_{i}\left(N-X_{11}\right) \quad i=1, \ldots, 5 \tag{25}
\end{equation*}
$$

Variance for the occurrence of retirements from vintage $i$ in year $j, X_{i j}$, can be calculated using the result given by Hogg and Craig (1965):

$$
\begin{equation*}
\operatorname{Var} Y=E[\operatorname{Var}(Y \mid X)]+\operatorname{Var}[E(Y \mid X)] \tag{26}
\end{equation*}
$$

Hence,

$$
\begin{align*}
& \operatorname{Var} X_{11}=N p_{1}\left(1-p_{1}\right) \\
& \operatorname{Var} X_{1 j}=E\left(\left(N-x_{11}\right) p_{j} \frac{\left(1-p_{j}\right)}{\left(1-p_{1}\right)}\right)+\operatorname{Var}\left(\frac{\left(N-x_{11}\right) p_{j}}{\left(1-p_{1}\right)}\right) \\
& =N p_{j}\left(1-p_{j}\right)+\frac{N p_{1} p_{j}^{2}}{\left(1-p_{1}\right)} \quad j=1, \ldots, m  \tag{27}\\
& \operatorname{Var} X_{i j}=E\left[\operatorname{Var}\left(X_{i j} X_{11}\right)\right]+\operatorname{Var}\left[E\left(X_{i j} X_{11}\right)\right] \\
& =E\left[A_{i-1}\left(N-X_{11}\right) p_{j}\left(1-p_{j}\right)\right] \\
& +\operatorname{Var}\left[\left(N-X_{11}\right) A_{i-1} p_{j}\right] \\
& =A_{i-1} N\left(I-F_{j} \backslash F_{j}\left(1-F_{1}\right)+\pi_{i-1}^{2} F_{j}^{2} N F_{1}\left(1-F_{1}\right)\right. \\
& i=2, \ldots, 6 \\
& j=1, \ldots, m \tag{28}
\end{align*}
$$

Covariances for the above quantities can be related in a similar manner, since the occurrence of subsequent retirements depends on $x_{11}$, Hogg and Craig (1965) state:

$$
\begin{equation*}
\operatorname{Cov}(Y, Z)=E[\operatorname{Cov}(Y \mid X), \operatorname{Cov}(Z \mid X)]+\operatorname{Cov}[E(Y \mid X), E(Z \mid X)] . \tag{29}
\end{equation*}
$$

Since in this case the events depend upon $X_{11}$, (29) reduces to

$$
\begin{equation*}
\operatorname{Cov}(Y, Z)=\operatorname{Cov}[E(Y \mid X), E(Z \mid X)] \quad . \tag{30}
\end{equation*}
$$

Hence,

$$
\begin{array}{ll}
\operatorname{Cov}\left(x_{11}, x_{1 j}\right)=-N p_{1} p_{j} & j=1, \ldots, m \quad(31) \\
\operatorname{Cov}\left(x_{11}, x_{i j}\right)=-N A_{i-1} p_{1}\left(1-p_{1}\right) p_{j} & i=2, \ldots, 6 \quad(32) \\
\operatorname{Cov}\left(x_{1 j}, x_{k \ell}\right)=N A_{k-1} p_{1} p_{j} p_{\ell} & =1, \ldots, m \\
& j=1, \ldots m \quad(33)  \tag{33}\\
& k=2, \ldots, 6 \\
& \ell=1, \ldots, m
\end{array}
$$

$\operatorname{Cov}\left(X_{i j}, X_{k \ell}\right)=N A_{i-1} A_{k-1} p_{1}\left(1-p_{1}\right) p_{j} p_{\ell}$

Finding the variance for the balances in years 1 through 6 combines the above results. Let

$$
\begin{align*}
B_{m} & =1+\sum_{i=1}^{m-1} A_{i} & & m=1, \ldots, 6  \tag{35}\\
\delta_{i j} & =B_{m} & & \text { if } \\
& =1 & & i=j=1 \\
k_{i j} & =i & & \tag{36}
\end{align*}
$$

$$
\begin{array}{rlrl}
\ell_{i j} & =j+1 & \text { if } & \\
& =i+j<n+l  \tag{38}\\
& =1+1 & & \\
i+j=n+1
\end{array}
$$

Thus,

$$
\begin{align*}
\operatorname{Var}(\text { Balance in year } 1) & =\operatorname{Var}\left[P\left(N-X_{11}\right)\right] \\
& =\mathrm{P}^{2} \operatorname{Var} \mathrm{X}_{11} \\
& =\mathrm{P}^{2} \mathrm{~Np}_{1}\left(1-\mathrm{p}_{1}\right) \tag{39}
\end{align*}
$$

Var (Balance in year m)

$$
\begin{align*}
= & \operatorname{Var}\left[P\left(N+\sum_{i=1}^{m-1} M_{i}-\sum_{i=1}^{m} \sum_{j=1}^{m-i+1} x_{i j}\right)\right] \\
= & P^{2}\left[\begin{array}{cccc}
m & m-i+1 \\
i=1 & \sum_{j=1}^{m} \delta_{i j}^{2} \operatorname{Var} x_{i j} \\
& +2 \sum_{i=1}^{m-1} & \sum_{j=1}^{m-i+1} & \sum_{k=k_{i j}}^{m} \\

\end{array}\right.
\end{align*}
$$

Comparison of Results Produced by Statistical Models With and Without Data Dependence

The decision rule for the size of the addition in each year which was derived in the previous subsection can be compared to what was actually produced by the Monte Carlo study. The additions produced by the computer, on the average, slightly understate the expected addition computed from formulas (14), (17), (20); (21); and (22).

Table 4. Comparison of additions produced by Monte Carlo study with additions expected under the statistical model

| Year | Mean of additions <br> from Monte Carlo study | Addition expected when <br> events are conditioned | oiff. |
| :---: | :---: | :---: | :---: |
| 2 | 14,526 | 14,530 | .006 |
| 3 | 28,033 | 28,130 | .32 |
| 4 | 44,597 | 44,750 | .34 |
| 5 | 61,311 | 61,370 | .09 |
| 6 | 74,628 | 75,890 | 1.6 |

The means and variances of the balances produced by the two statistical models are compared in Table 5. The average of the mean balance assuming no data dependence and sample mean of the variance of balances assuming no data dependence were found by averaging the values produced by Equations (6) and (9) respectively to each Monte Carlo sample. The means and variances for the data-dependent case are taken from applying Equations (24), (27), and (28).

The Monte Carlo study produces means (simulated balances) assuming no data dependence which in the years examined understate the target balance from Equation (24). The variances of the balances obtained assuming no data dependence neglect the fact that the price per unit, $P$, is a constant multiplied times the number of units involved at a given point in time.

Table 5. Comparison of means and variances produced by the two statistical models

No data dependence Data dependence
Average of Average of Mean Variance of \% \% Year mean of variance of balance balance Diff. Diff.

| 1 | 996,385 | 10,843 | 996,370 | 106,567 | 0 | 882 |
| ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| 2 | 996,375 | 17,824 | 996,370 | 179,305 | 0 | 906 |
| 3 | 996,292 | 44,155 | 996,370 | 445,320 | 0 | 909 |
| 4 | 996,148 | 82,927 | 996,370 | 831,370 | 0 | 903 |
| 5 | 996,091 | 130,056 | 996,370 | $1,360,598$ | 0 | 946 |
| 6 | 996,098 | 178,442 | 996,370 | $2,086,224$ | 0 | 1069 |

The variance formula (9) given in White's calculations assumes the additions $N_{j}$ may be in units or dollars. If the additions and balances are in dollar values, the dollar values are the products of the number of units and the price per unit. This qualification results in the following modification to white's work:

$$
\begin{align*}
& E\left(B_{k}\right)=P \sum_{i=1}^{k} N_{i}\left(1-\sum_{j=1}^{k-i+1} \pi_{j}\right)  \tag{41}\\
& \operatorname{Var}\left(B_{k}\right)=P^{2} \sum_{i=1}^{k} N_{k-i+1}\left(1-\sum_{j=1}^{i} \pi_{j}\right)\left(\sum_{j=1}^{i} \pi_{j}\right)  \tag{42}\\
& \operatorname{Cov}\left(B_{k} \quad B_{k^{\prime}}\right)=P^{2} \sum_{i=1}^{k} N_{k-i+1}\left(\sum_{j=1}^{i} \pi_{j}\right)\left(1-\sum_{j=1}^{k \prime-k+i} \pi_{j}\right) \tag{43}
\end{align*}
$$

The expectation does not differ from what White found in Equation (6). However, the variances and covariances in (42) and (43) are $P$ times the results in Equations (9) and (10) respectively.

Taking White's nondata-dependent theory and multiplying the variance given in Equation (9) by P would produce substantial changes in the dispersion of the balances with respect to the mean and variance. Table 3 revealed in applying Equation (9), the observations are more dispersed than theory would expect. If the variances in (9) were recalculated using (42), 6, 6, and 4 balances for test years 11, 13, and 15 respectively would fall outside $\mu \pm 2 \sigma$. This step is a dramatic improvement over the results in Table 3. A chisquare test applied using the revised variances and covariances would result in rejection of 6 out of 50 samples at the . 05 level, a great improvement over the rejection of 49 out of 50 sampies previounsiy.

In the real world, the determination of the price per unit could make implementation difficult. This problem coupled with the fact that modeling with data dependence produces additional covariance terms which go to zero if there is no data dependence causing this modeling to produce higher variances than in the other case.

When applying nondata-dependent theory developed by White (1968), the additions were assumed to be constants with
no variability. As can be seen from Table 6, the actual additions in this case have a wide variability, even greater than the variability of the balances.

Table 6. Sample means and sample standard deviations for actual additions and actual balances

|  | Additions <br> Year |  | Sample <br> mean | Sample stan- <br> dard deviation |
| :---: | :---: | :---: | :---: | :---: |
| 1 | $1,000,000$ | 0 | Sample <br> mean | Balances <br> Sample stan- <br> dard deviation |
| 2 | 14,526 | 311.3 | 996,329 | 166.9 |
| 3 | 28,033 | 540.4 | 996,334 | 169.8 |
| 4 | 44,597 | 659.1 | 996,319 | 174.9 |
| 5 | 61,311 | 855.4 | 996,312 | 207.4 |
| 6 | 74,628 | 718.9 | 996,309 | 203.6 |
| 7 | 81,993 | 756.1 | 996,302 | 208.7 |
| 8 | 86,126 | 868.2 | 996,287 | 222.5 |
| 9 | 89,429 | 812.3 | 996,281 | 216.3 |
| 10 | 92,984 | 931.0 | 996,281 | 225.6 |
| 11 | 95,606 | 850.6 | 996,274 | 241.0 |
| 12 | 97,831 | 920.8 | 996,258 | 262.6 |
| 13 | 99,530 | 967.5 | 996,271 | 259.6 |
| 14 | 100,847 | 975.4 | 996,268 | 263.5 |
| 15 | 101,534 | 1071.9 | 996,242 | 267.2 |

The nondata-dependent theory produces a mean and variance for the balance each year for each sample. Comparison with data-dependent theory in Table 5 has shown that for this Monte Carlo study the variances of the balances assuming no
data dependence need to be larger. To determine what the variances should be, the variability of the estimates of the mean and variances calculated from Equations (6) and (9) is compared in Table 7 for selected years.

Table 7. Sample means and sample standard deviations for means and variances of balances assuming no data dependence

|  | Mean of balances assuming <br> no data dependence |  | Variance of balances <br> assuming no dependence |  |
| ---: | :--- | :--- | :--- | :---: |
|  | Mean | Standard deviation | Mean |  |

The sample variance of the mean assuming no data dependence should be a more accurate reflection of what the variance in this situation should be than the variances obtained from Equation (9). To relate these quantities, a regression analysis was performed for

$$
\begin{equation*}
Y=\alpha+\beta X+\varepsilon \tag{44}
\end{equation*}
$$

where
$Y=$ sample variance of the mean obtained from Equation (6).
$X=$ sample mean of the variance obtained from Equation (9).
$\varepsilon=$ error term.
The estimates using the data in Table 7 are $\hat{\alpha}=2.98977$ E 06 and $\hat{\beta}=2.0348$.

Table 8 reveals that the $F$ test is not significant. Even though this regression attempt to relate the two quantities has not been successful the same approach can be taken with the covariance terms.

Table 8. Results of regression analysis for variance

| Source | df | SS | MS | F |  |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Regression | 1 | 1.16 E 11 | $1.16 \mathrm{E} \mathrm{l1}$ | 1.27 |  |
| Residual | 3 | 2.73 E 11 | 9.09 E 10 |  |  |
| $\quad$ Total |  | 3.89 E 11 |  |  |  |

Table 9 gives comparisons for the covariance terms in years 11, 13, and 15. Covariances between years $i$ and $j$ can be estimated by the Monte Carlo study via the following relationship:

$$
\begin{equation*}
\operatorname{cov}\left(B_{k} \quad B_{k}:\right)=\Sigma X_{i}^{\prime} y_{i}^{\prime}-n \bar{X}^{\prime} \bar{Y}^{\prime} \tag{45}
\end{equation*}
$$

where

$$
\mathrm{B}_{\mathrm{k}^{\prime}} \mathrm{B}_{\mathrm{k}}{ }^{\prime}=\text { balance in years } \mathrm{k} \text { and } \mathrm{k}^{\prime} \text { respectively. }
$$

$$
\begin{aligned}
X_{i}^{\prime}= & \text { estimate of mean in year } k \text { for sample } i \text { produced } \\
& \text { from Equation (6). } \\
Y_{i}^{\prime}= & \text { estimate of mean in year } k^{\prime} \text { for sample i produced } \\
& \text { from Equation }(6) . \\
n= & \text { number of samples. } \\
\bar{X}^{\prime}= & \sum_{i=1}^{n} X_{i}^{\prime} \\
\bar{Y}^{\prime}= & \sum_{i=1}^{n} Y_{i}^{\prime}
\end{aligned}
$$

Table 9. Comparison of covariance terms for balance

| Years | Covariance calculated <br> from (45) | Sample mean of <br> covariances from (10) |
| :--- | :---: | :---: |
| 11,13 | 3.3554 E 08 | 230,949 |
| 11,15 | 3.6909 E 08 | 160,337 |
| 13,15 | 3.0198 E 08 | 228,752 |

The quantities in Table 9 can be related by a regression equation

$$
\begin{equation*}
Y=\alpha+\beta X+\varepsilon \tag{46}
\end{equation*}
$$

where
$Y=$ covariance terms calculated from (45).
$X=$ mean of covariance terms calculated from (10).
$\varepsilon=$ error term.
This produces $\hat{\alpha}=-8114.96$ and $\hat{\beta}=91.35$.

This analysis given in Table 10 is no more successful in producing a significant $F$ test. While the number of observations in each case is limited, this procedure is a workable method of determining what variances and covariances should be in a data-dependent situation using nondata-dependent formulas.

Table 10. Regression analysis for covariance terms

| Source | df | SS | MS | F |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| Regression | 1 | 2.6804 E 07 | 2.6804 E 07 | 2.48 |  |
| Residual | 1 | 1.8007 E 07 | 1.8007 E 07 |  |  |
| Total | 1 | 3.7611 E 07 |  |  |  |

Problems in Implementing Computer Decision Rule

The decision rule used by the PGM computer program uses events which will logically occur in the future to determine what the infusion in each year will be. Since this is the case, a statistical modeling of the process the computer goes through in data-dependent situations cannot be achieved. However, the additions and balances the computer produces can be compared to what one would expect.

For example, in year 2 the addition in dollar values is P $X_{12}\left(1-p_{1}\right)$.

$$
\begin{align*}
& E\left(\text { Additions in year 2) }=E\left[P\left(\frac{X_{12}}{1-p_{1}}\right)\right]=\frac{P}{1-p_{1}} E\left(X_{12}\right)\right. \\
& \quad=\frac{N P p_{2}}{1-p_{1}}  \tag{47}\\
& E\left(\text { Balance in year 2) }=E\left[P\left(N-X_{11}-X_{12}+M_{1}-X_{21}\right)\right]\right. \\
& \quad=P\left[N\left(1-p_{1}-p_{2}\right)+\frac{N p_{2}}{1-p_{1}}\left(1-p_{1}\right)\right] \\
& \quad=P N\left(1-p_{1}\right) \tag{48}
\end{align*}
$$

This process can be repeated for each year. The results of computing these expectations for each year are found in Table 11. The average of the additions produced by the computer given in Table 6 are remarkably close to what one would expect them to be. However, the computer produces a smaller balance on the average as shown in Table 6 than one would expect. In the course of computing retirements for each vintage, it appears the retirements $X_{i j}$ are being overstated by the computer. It is recommended that further scrutiny be given to the PGM program to examine the process used to simulate retirements.

Table ll. Expected additions and balances using the computer decision rule

| Year | Expected addition | Expected balance |
| :---: | :---: | :---: |
| 2 | 14,570 | 996,270 |
| 3 | 28,120 | 996,420 |
| 4 | 44,740 | 996,420 |
| 5 | 61,370 | 996,420 |
| 6 | 74,630 | 996,410 |
| 7 | 82,040 | 996,410 |
| 8 | 85,920 | 996,420 |
| 10 | 89,520 | 996,420 |
| 11 | 92,810 | 996,420 |
| 12 | 95,670 | 996,430 |
| 13 | 98,000 | 997,830 |
| 14 | 100,980 | 997,920 |
| 15 | 997,580 | 997,480 |

## ABILITY OF THE BALANCES METHOD TO DETECT CORRECT DISPERSION AND AVERAGE SERVICE LIFE

Many depreciation analysts use the simulated-plant record balances method to select the correct dispersion and average service life. The choice is made by picking the retirement dispersion and average service life which minimize the sum of squares differences between the actual and simulated balances. Some practitioners feel that the combination of dispersion and average service life which produces this minimum sum of squares is a unique best-fitting representation of mortality characteristics.

To examine this notion, the Monte Carlo studies discussed in the previous sections were analyzed using the SPR balances method and the chi-square statistic. A computer program was written to analyze these data combining work done by White and Cowles (1972) and White (1968). The program documented by White and Cowles (1972) performs the SPR analysis, giving the average service life which minimizes the sum of squares difference between actual and simulated balances for each Iowa type curve. The program developed by White (1968) finds the chi-square statistic after the dispersion and average service life are input, The resulting computer program determines the chi-square test statistic for each of the 31 Iowa type curves using the test years specifieu dy the dalañes method.

Since the data in these Monte Carlo studies are very regular with little variation built in, they cannot be supposed to reflect a real world situation which is affected by factors such as inflation, price variation, or economic uncertainty. Nevertheless, from analyzing the Monte Carlo studies, the idea of producing a unique best-fitting representation of the data can be clarified or dispelled.

Monte Carlo Study With Constant Infusions

These data were generated from an RI Iowa type curve with a ten year average service life. One hundred units priced at $\$ 1$ each were placed in service every year for ten years. These samples are listed in the Appendix, consisting of samples 1 to 100. Two samples out of 100 were rejected by the chi-square statistic at the . 05 level using the Rl type curve and average service life produced by the sum of squares criterion.

In spite of the regularity of these data, the balances method seldom selected the Rl-10 curve from which the data are known to be generated. In Table 12, a distribution of service lives for the RI curve produced by the sum of squares criterion is given.

This vairation from the true average service life by as much as $\pm 10 \%$ is surprising and could have a significant effect on the depreciation accrual for a property with a longer service life.

Table 12. Number of samples generating the given average service life for an Rl curve by the SPR balances method for samples 1 through 100

| ASL | Frequency |
| :---: | :---: |
| 9.2 | 1 |
| 9.3 | 1 |
| 9.4 | 4 |
| 9.5 | 7 |
| 9.6 | 8 |
| 9.7 | 8 |
| 9.8 | 13 |
| 9.9 | 7 |
| 10.0 | 5 |
| 10.1 | 4 |
| 10.2 | 9 |
| 10.3 | 7 |
| 10.4 | 5 |
| 10.5 | 6 |
| 10.6 | 7 |
| 10.7 | 4 |
| 10.8 | 0 |
|  | 4 |

In Table 13, it is found that the R1 dispersion is not always the curve which produces a minimum sum of squares. In fact in only $10 \%$ of the samples did the $R 1$ curve produce the minimum sum of squares differences. The sum of squares criterion has the $R 1$ curve ranked as low as eleventh out of the 31 Iowa type curves. The results obtained from the chisquare statistic do not produce ranking that differs greatly from the sum of squares criterion.

Monte Carlo Studies With Data Dependence

Samples 101 through 150 in the Appendix were generated from an Ll-10 Iowa type corve. One thousand units priced at \$1 each were placed in service in year one, and each sample was specified to have no growth. Using test years lly 13 , and 15, the chi-square statistic assuming no data dependence rejected 5 out 50 samples when examining the Ll curve and average service life produced by the sum of squares criterion.

Table 14 gives the distribution of service lives produced for the $L$ l curve by the sum of squares criterion. In this case, the average service life varies up to $\pm 5 \%$ from the known average service life. Again if this property had a longer average service life, such a discrepancy in estimating the average service life could play havoc with the depreciation rate.

Table 13. Chi-square ranking compared to sum of squares ranking for Rl curve for samples 1 through 100

Chi-square statistic ranked in ascending order for Rl curve for samples 1 through 100

|  |  | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 |  |

|  |  | 11 | 11 | 7 | 6 | 6 | 15 | 10 | 23 | 7 | 2 | 1 | 1 | 100 |

Table 14. Number of samples generating the given average service life for an $L 1$ curve by the SPR balances method for samples 101 through 150

| ASL | Frequency |
| :---: | :---: |
| 9.6 | 1 |
| 9.7 | 5 |
| 9.8 | 3 |
| 9.9 | 8 |
| 10.0 | 11 |
| 10.1 | 10 |
| 10.2 | 7 |
| 10.3 | 2 |
| 10.4 | 3 |

Table 15 compares results produced by the sum of squares criterion with those produced by the chi-square statistic. In this case only 5 out of 50 samples produced the minimum sum of squares differences for the $L l$ dispersion. The Ll dispersion actually ranks as low as tenth by both sum of squares and chi-square.

For the other no growth Monte Carlo study with 100,000 units priced at $\$ 10$ each, the results were different. The chi-square statistic rejected 49 out of 50 samples at the . 05 level. However, for all fifty samples the chi-square statistic and sum of squares differences were a minimum for
the Ll dispersion. The average service life for the L l dispersion produced by the sum of squares criterion was 10.0 in every case.

Table 15. Chi-square ranking compared to sum of squares ranking for Ll dispersion for samples 101 through 150

Chi-square ranked in ascending order for $L 1$ curve

While the first no growth Monte Carlo study produced more statistically acceptable results, the SPR balances method had difficulty in selecting the correct choice of dispersion and average service life. In many cases, a large number of curves were grouped near the curve which produced a minimum sum of squares difference with little difference in their respective sum of squares differences and even less in the indices of variation. More accurate conclusions would be gained by subjectively analyzing several curves as to the average service life and position and height of the mode of the density function.

When given Monte Carlo studies where the values were smaller in a hundred or thousand dollar units, the balances method had greater difficulty in selecting the proper dispersion than when the additions were larger. The chi-square test however performed better in the former case than in the latter. The problems associated with the chi-square modeling were discussed at length in the section involving data dependence. If the chi-square modeling incorporated the price per unit $P$ as a separate quantity from the additions the analysis could be greatly improved. Whether this phenomena would occur in other cases by varying the size of the initial installation would be a subject of great interest for further research.

## SUMMARY AND CONCLUSIONS

The simulated plant-record method is the only technique used to analyze semi-actuarial data which gives estimates of both the retirement dispersion and average service life. Practitioners in industry have relied upon the SPR method to produce a unique best fitting curve. In the past statistical modeling has achieved limited success in analyzing the SPR method. Exploration of these problems has produced the following conclusions:
(i) When the data are not dependent on the occurrence of retirements from one vintage to the next, the statistical modeling proposed by White is appropriate. The balances are normally distributed with means and variances given in equations (6) and (9) respectively.
(ii) When varying the shape of the tolerance region from ellipsoidal to a rectangular parallelepiped, little change is found. For ease of computation, the ellipsoidal shape is preferred.
(iii) When examining data-dependent situations, White's modeling produces more frequent rejection of the Monte Carlo samples than theory would expect.
(iv) If one were to separate the price per unit from the dollar value of each account, the data-dependent case would produce larger variances and covariances
and could be analyzed more successfuly by White's model.
(v) In the data-dependent case variability of the means produced by the Monte Carlo studies can be used to estimate true variability for data-dependent observations.
(vi) The SPR balances method does not produce a unique best fitting curve. Instead several curves should be analyzed before choosing one as a best fit.
(vii) On the basis of these data discussed herein, it appears the SPR balances method estimates the correct dispersion and average service life with greater precision when the dollar values involved are of greater magnitude than when the dollar values are smaller in magnitude.

The conclusions drawn from this study raise a number of questions that warrant further investigation. The assumption that all vintages come from a homogeneous population has not been explored in this study. However, for real world application, this assumption is almost certainly violated. Modifications to the statistical development presented would be of interest.

Separating the price component from the analysis for computation of the variance and covariance could present quite a problem in industrial applications. Choice of a variable
price for each year could be used to approximate conditions such as inflation or economic uncertainty.

The PGM computer program was found to produce more retirements than could be expected theoretically. The decision rule in data-dependent cases for each year's addition closely approximates the additions produced by the Monte Carlo studies. However, before any further studies are made using this program, a better understanding of the logic should be undertaken.

The statistical modeling presented for data-dependent observations is conditioned on retirements which occur during the first year. Conditioning on retirements which occur in later years would be a logical extension of this work. This process would be of limited value for real world situations.

Further, Monte Carlo studies in other situations than the no growth would be of aid in determining how the balances method is affected by the size of initial installation and price per unit. Other areas which could be explored are quantifying a scale for the index of variation or empirically substantiating the scales given for the conformance index or retirements experience index.

## ACKNOWLEDGMENTS

The author is deeply indebted to Dr. Harold A. Cowles who fostered my interest in the field of engineering valuation and who provided advice, counsel, encouragement, and consolation during the course of this research. The statistical development presented herein owes much to the insight and interest of Dr. Herbert T. David.

I am grateful to Dr. Keith L. McRoberts and Dr. Chester W. Fitch of Western Michigan University who generously provided computer funds without which this research could not have been completed. Thanks go to Dr. Aly A. Mahmoud and the Power Affiliate Program which furnished financial support of this investigation.

I am indebted to my parents, Charles G. and Florence Sledge Hallaman, who have provided encouragement and support throughout my acautmic aareer.

Finally, my deepest thanks and appreciation go to my husband, Wendell, who in the course of pursuing his own research offered patience, understanding, and encouragement during all phases of this study.

## APPENDIX: LISTING OF SAMPLES GENERATED FOR MONTE CARLO STUDIES

| Sample | Year | Additions (Middle of year) | Retirements (During year) | Balances (End of year) |
| :---: | :---: | :---: | :---: | :---: |
| 1 | 1 | 100 | 2 | 98 |
|  | 2 | 100 | 3 | 195 |
|  | 3 | 100 | 5 | 290 |
